- **Enteroicellobacillosis** occurs primarily in calves under 4 d of age and is characterized clinically by an acute, profuse liquid diarrhea. Recovery following treatment usually occurs in 2 d. Outbreaks occur in beef and dairy calves. Rotavirus and coronavirus diarrhea usually occur in calves over 5–10 d of age and up to 3 weeks of age. Explosive outbreaks occur, characterized by an acute profuse liquid diarrhea with recovery in 2–4 d. Recovery is assisted by oral fluid therapy.

- **Cryptosporidiosis** occurs in calves from 5–15 d of age and is characterized by a persistent diarrhea which may last for several days. The cryptosporidium may be detected by Giemsa stain of fecal smears or by fecal flotation.

**BVD**. Whether or not the BVDV causes clinically significant diarrhea with lesions of the small intestine of calves 3–6 weeks of age is unknown. Diagnostic laboratories report the presence of intestinal lesions such as villous atrophy and crypt cell destruction in calves 3–6 weeks of age which have been affected with an intractable diarrhea and from which the BVD virus was isolated from the feces. However, to date there is no evidence of a cause and effect relationship.

**Piglets**

- **TGE** occurs most commonly in piglets under 1 week of age and explosive outbreaks are common. There is acute profuse diarrhea and vomiting. Affected piglets may continue to nurse for several hours after the onset of the diarrhea. The case-fatality rate is high in piglets under 7 d of age; older pigs commonly survive.
The treatment of viral diarrheas in newborn farm animals is essentially the same as described for acute undifferentiated diarrheas of newborn calves. There is no specific therapy for viral diarrhea, but antimicrobial agents may be used both orally and parenterally for the possible occurrence of secondary enteric and systemic bacterial infections. In the absence of complications, recovery from viral enteritis usually occurs without specific treatment in 2-5 d, which parallels the replacement of the villous epithelial cells whose complete replacement and maturation requires several days after the cessation of diarrhea.

The withholding of milk for 24-48 h is beneficial, but often not possible or practical with nursing beef calves or litters of pigs. Milk can be easily withheld from hand-fed calves and replaced with oral fluids and electrolytes.

Oral and parenteral fluid therapy (as indicated is essential and details are described in the sections on colibacillosis and fluid and electrolyte therapy). Affected foals may require fluid and electrolyte therapy for up to 72 h. A glucose-glycine electrolyte formulation is an effective fluid therapy for pigs affected with experimental rotaviral diarrhea. The formula is: glucose 67.53%, sodium chloride 14.34%, glycine 10.3%, citric acid 0.8%, potassium citrate 0.2% and potassium dihydrogen phosphate 6.8%. A weight of 64 g of the above is dissolved in 2 L water to produce an isotonic solution.

When possible, affected animals, particularly calves, should be isolated from calving grounds and other newborn calves, which are susceptible up to 3 weeks of age. When outbreaks of the disease occur in any species, the principles of good sanitation and hygiene should be emphasized to minimize the spread of infection.

CONTROL
The principles of control of viral diarrhea are similar to those described for acute undifferentiated diarrhea of newborn calves:

- Reduce infection pressure
- Insure adequate colostral intake
- Vaccinate the dam to induce specific immunity in the colostrum (passive immunization).

Management and colostral intake
The management of pregnant animals at the time of parturition must insure that the degree of exposure of the newborn to infectious agents is minimized. Control of population density to avoid overcrowding, and attention to sanitation and hygiene are important. Because infected neonates excrete large numbers of viral particles for several weeks, effective control is dependent on management of the environment of the newborn species with particular emphasis on hygiene. The ingestion of adequate quantities of good quality colostrum as soon after birth as possible is also important.

Vaccination
Two major approaches have been used to provide specific immunity for the control of rotavirus and coronavirus diarrhea in calves:

1. Stimulation of active immunity by vaccinating the newborn calf with an oral vaccine containing the modified live viruses (MLVs)
2. Enhancement of lactogenic immunity by vaccinating the dam during pregnancy (passive immunization).

Oral vaccines to newborn calves
A MLV rotavirus vaccine for oral administration to calves immediately after birth has been available commercially for many years. Initially, good results were claimed but vaccine field trials did not include contemporary controls and the efficacy of the vaccine was uncertain. The incidence of diarrhea in herds not vaccinated in the previous year was compared with the incidence during the year of vaccination, which is inadequate to assess the efficacy of the vaccine.

Field trials using the oral vaccine indicate a failure of protection of calves against rotavirus infection and rotavirus--coronavirus infection. Effective oral vaccination of calves may be hindered by the presence of specific antibodies in the colostrum -- the colostrum barrier -- and may explain the failure of the vaccine under field conditions. The intestinal antibody response of young calves to an enteric viral infection is associated with the production of IgM and IgA antibodies locally in the intestine. This response is absent or diminished in calves which have ingested colostrum with specific antibodies to the viruses. Most of the efficacy trials with the vaccine were carried out on colostrum-deprived gnotobiotic calves which were vaccinated orally at birth and experimentally challenged a few days after birth. It is probably futile to vaccinate calves orally immediately after birth, particularly in herds where the disease is endemic because the colostrum will contain high levels of specific antibodies.

Fecal shedding of oral vaccine rotavirus seldom occurs after oral inoculation of gnotobiotic calves with a commercial modified live bovine rotavirus-bovine coronavirus vaccine. Because of low shedding of virus in gnotobiotic calves which do not have the interfering effects of colostral antibodies, it seems unlikely that vaccine rotavirus will be shed in quantities from orally vaccinated conventional calves which have ingested colostrum containing antibody. Thus detection of the
Viral diseases characterized by alimentary tract signs

Vaccination of pregnant dam (passive immunization)

Vaccination of the pregnant dam to enhance specific colostral immunity can provide passive protection against enteric viral infections in newborn farm animals. The success of this method depends on the continuous presence of a sufficient amount of specific antibody to the rotavirus and coronavirus in the intestinal lumen. Normally, the colostral levels of antibody are high in the first few milkings after parturition. However, there is a rapid decline in colostral antibodies to below protective levels within 24-48 h following parturition. Most cases of rotavirus and coronavirus diarrhea occur from 5-14 d after birth when the antibody levels in the post-colostral milk are too low to be protective.

The parenteral vaccination of the pregnant dam before parturition with a rotavirus and coronavirus vaccine will usually increase the level and duration of specific antibody in the colostrums. There is a need for a vaccine which when given to pregnant cattle will initially result in protective levels of specific antibody to the rotavirus and coronavirus in the colostrum, and then in the milk for a sufficient period such as 10 d to 3 weeks, the period in which animals are most susceptible to these viral diarrhea. The use of a modified live rotavirus-coronavirus vaccine stimulated a small but insignificant increase in colostral and milk antibodies. However, by 3 d after parturition, the rotavirus and coronavirus antibody titers in the milk of vaccinated heifers had declined to low or undetectable levels.

Inactivated rotavirus vaccines given to pregnant cows in the last trimester will significantly increase antitoxivirus antibody in colostrum and milk from vaccinated dams compared to controls, but the severity of diarrhea may be the same in calves from both groups. The increased milk antibody delays the establishment of infection but does not reduce the severity of clinical disease which was experimentally induced. An inactivated oil-adjuvanted rotavirus vaccine given 1 month before calving to beef cattle significantly reduced the morbidity and mortality in 16 of 17 herds with a total of 4066 cows.

Experimental studies of maternal bovine rotavirus vaccines

The use of an adjuvanted rotavirus vaccine given simultaneously intramuscularly and by the intramammary route significantly enhanced serum, colostrum and milk rotavirus antibody titers, whereas intramuscular vaccination with a commercial modified live rotavirus–coronavirus vaccine did not. Colosum supplements, from the cows vaccinated by the intramammary and intramuscular routes, led to rotavirus-challenged calves at a rate of 1% of the total daily intake of milk, provided protection against both diarrhea and shedding. The 30-day milk antibody titers from these experimental cows were also considered to be protective for calves by which time the calves should have developed a high degree of age-specific resistance to rotavirus infection. The use of an inactivated rotavirus vaccine in an oil adjuvant given to pregnant cows 60-90 d before calving and repeated on the day of calving resulted in a significant increase and prolongation of colostral antibodies up to 28 d after calving. Diarrhea in calves from vaccinated cows was less common and less serious. Similar results were obtained with a combined inactivated adjuvanted rotavirus and E. coli vaccine. Similar results have been achieved by vaccination of pregnant ewes. Vaccination of ewes can result in an elevation of specific colostral antibody and prolong the period over which the antibody is present in the lumen of the intestines of the lambs. The vaccination of cows with a monovalent vaccine results in a heterotypic response to all serotypes of rotavirus to which the animals have been previously exposed, which suggests that single serotype vaccination may be sufficient.

The lactogenic antibody responses in pregnant cows vaccinated with recombinant bovine rotavirus-like (VLPS) of two serotypes or inactivated bovine rotavirus vaccines have been evaluated. Bovine rotavirus antibody titers in serum, colostrum and milk were significantly enhanced by the use of triple-layered VLPs and inactivated vaccines but higher antibody responses occurred in VLP vaccinated cows.

Bovine coronavirus vaccine

An oil adjuvanted vaccine containing bovine coronavirus antigen to enhance lactogenic immunity in the calf by vaccinating pregnant cows and heifers between 2 and 12 weeks before calving increased serum antibody in the dams which was reflected in a similar increase in the titer and duration of specific antibody in colostrum and milk for up to 28 days after calving. The overall response was dependent on an adequate antigen payload being incorporated within the single dose vaccine.

Commercial bovine rotavirus-coronavirus and E. coli F5 (K99+) vaccines

The original rotavirus and coronavirus vaccines for use in pregnant cows to provide passive immunization were not sufficiently efficacious because of the rapid decline in specific colostral antibodies, which renders the calves susceptible to the viral diarrhea several days after birth. The relative success of the enterotoxigenic K99+ E. coli bacterium has resulted in a shift of the epidemic curve for acute diarrhea in calves under 30 d of age from a few days of age to 2-3 weeks of age.

More recently developed vaccines are efficacious. An inactivated combined vaccine against rotavirus, coronavirus and E. coli F5 (K99+) administered 31 days before the first expected calving date has been evaluated and compared to controls. There was a significant increase in serum antibody against all three antigens in vaccinated animals, which was accompanied by increased levels of protective antibodies to rotavirus, coronavirus, and E. coli in their colostrum and milk for at least 28 days. The levels of specific rotavirus and coronavirus antibodies in the milk of vaccinated cows were greater than a four-fold higher than in the control cows for at least 28 days after calving.

The primary vaccination of pregnant cows with a trivalent commercial vaccine containing live attenuated bovine rotavirus and coronavirus and E. coli F5 followed by an annual booster at 6 and 3 weeks before calving, or using the same protocol with an inactivated trivalent vaccine resulted in significant increase in the serum antibody of all vaccinated animals compared to controls. The antibody titers were higher in cows receiving the live vaccine compared to those receiving the inactivated vaccine. The colostral antibodies against all three antigens increased in all live vaccinated groups whereas inactivated vaccinated animals had only significant increases in F5 titers. The colostrum of live vaccinated cows contained much higher specific antibody titers. Thus the modified-live virus vaccine can significantly enhance the specific response to rotavirus and E. coli F5 after a primary vaccination followed by a booster annually.

Feeding 2 liters of colostrum within 12 hours after birth, from cows vaccinated 8 weeks before calving with an inactivated vaccine containing rotavirus, coronavirus and E. coli K99+/F4 antigens, is efficient in raising the serum antibody titer of calves to a high level, and, thus, protecting them against rotavirus infections which occur in the first few weeks of life.

Stored colostrum

The high levels of viral antibody in the colostrum of the first two milkings of cows can be used to advantage in hand-fed calves. The daily feeding of stored colostrum from the first few milkings of cows from the affected herd will reduce the incidence of clinical disease in the
calves. The colostrum must be fed daily because rotavirus antibody is not retained in the intestinal lumen for more than 2-3 d. In affected herds the specific antiviral antibody in the stored colostrum may be sufficient to prevent the disease if colostrum is fed daily for up to 20-30 d. If a large number of cows are calving over a short period of time, the colostrum from immunized cows can be pooled and fed to the calves daily. Even small amounts of colostrum from immunized cows are efficacious if mixed with cows’ whole milk or milk replacer. This supplemental feeding of colostrum may be required for only 3-4 weeks, since older calves generally possess a high degree of age-specific resistance to rotavirus infections.

Systemic colostral antibody
For many years it was uncertain if circulating colostral antibody in calves was transferred back into the intestinal tract. Evidence shows that passive immunity to calf rotavirus diarrhea can be achieved by adequate calf serum colostral antibody titers. Calves fed colostrum on the first day of life had significant rotavirus antibodies in colostrum and milk.

Subunit vaccines
Subunit rotavirus vaccines consisting of virus-like particles given parenterally can enhance bovine rotavirus antibody titers in serum, colostrum and milk. Subunit vaccines offer advantages over conventional modified-live or inactivated vaccines including:

- Exclusion of adventitious agents associated with live vaccines
- Consistent production of outer capsid proteins
- Genetic engineering to allow updating of efficacious vaccines for boosting lactogenic immunity. Field studies to evaluate the vaccine under naturally occurring conditions have not yet been carried out.

Chicken egg yolk immunoglobulin
Preliminary studies on the protective action of anti-rotavirus chicken egg yolk immunoglobulins given orally to calves against experimental rotavirus infections in neonatal calves have been reported. Treated calves had increased body weights and the number of calves shedding high titers of rotavirus in the feces was decreased compared to control calves.

**REFERENCE LITERATURE**

**REFERENCES**

Viral diseases characterized by alimentary tract signs

66. The virus was isolated from the feces of sambar deer, waterbuck in a wild animal habitat, and from a white-tailed deer on a wildlife farm in Ohio. In a serological survey of coronaviruses among wild deer, 8.7% and 6.6% of sera from male deer in Wyoming and from white-tailed deer in Ohio, respectively, were seropositive against the wildlife isolates and selected bovine coronaviruses. Thus coronaviruses exist in wild ruminants which may be a source of infection transmissible to cattle.

Morbidity and case fatality rates
The morbidity rate may be as high as 30–50% within a few days after the first case is encountered, and up to 100% after 1 week. The case–fatality rate is less than 1%. A typical outbreak may last for 1–2 weeks and in Sweden, 75% occur between November and January. The disease is important in dairy herds because, although few animals die of the disease, it may cause serious loss of body condition and milk flow. In mild epidemics, the maximum decrease in milk production compared to a theoretical lactation curve ranges from 6–11%. The overall decrease in milk production may persist for 8–15 d, after which time milk production levels are regained. In severe epidemics, the maximum decrease in milk production may be as high as 30% and may last for up to 28 d.

Outbreaks of the disease diagnosed by farmers exhibit space–time clustering within a 30-day time and a 5.5 km radius. Large herds with more than 60 cows and a history of an outbreak in the previous year were at increased risk of an outbreak. In Sweden, one-third of the affected herds had experienced an outbreak within the previous 4 years and 18% had a least one further outbreak during the following 2 years.

Methods of transmission
Feces from clinical cases or clinically normal carriers are the source of infection, and contamination of feed or drinking water is the method of spread. In France, the disease occurs on small dairy farms where the surface area is smaller than 2.3 m²/cow. The disease is highly contagious and is introduced to farms by human visitors, carrier animals and fomites. Infection of the respiratory tract with the bovine coronavirus may enhance the transmission of the infection in addition to the usual fecal–oral route of transmission of enteric pathogens.

Experimental reproduction
Both winter dysentery and calf diarrhea can be reproduced using the same strain of BCV. Calf diarrhea and winter dysentery strains of the virus can cause diarrhea in cattle.
in adult cows in conjunction with host or environmental factors. Winter dysentery can be reproduced in seronegative lactating dairy cows by direct contact with an experimentally infected calf. All experimental cattle shed the virus in the feces at the onset of profuse watery diarrhea with small amounts of blood in the feces of the most severely affected animals including both cows and calves. The cows are commonly more depressed, and their appetites are decreased which is associated with small amounts of blood in the feces. Following infection all cattle will produce early interferon type 1 in serum and in nasal secretions and milk. All cattle develop high IgM antibody responses and long-lasting IgA antibody responses both systemically and locally. Prolonged IgM antibody responses occur in all infected cattle. The IgA antibody response in serum may be detectable for up to 17 months after infection. Bovine-specific IgG can be detected in all cattle during the experimental period of up to 22 months.

**Risk factors**

Host and environmental risk factors

The cow-level risk factors for the development of winter dysentery in dairy cattle have been examined. The likelihood of developing disease increased as the ELISA value for bovine coronavirus (BCV) antigen detectable in feces increased. Pregnant cattle were less likely to develop the disease compared with nonpregnant animals. Cows with high acute antibody titers to BCV which seroresponded had greater odds of developing disease, compared with cows with lower titers.

Some herd-level risk factors have been identified in dairy herds which have been exposed to the BCV and have experienced outbreaks of the disease. The factors which appeared to increase a herd’s risk for the disease include: an increase in herd prevalence of adult cows that had a four-fold or more increase in BCV serum IgG antibody titer, increase in herd prevalence of adult cows that had a four-fold or more increase in bovine viral diarrhea titer; housing cattle in tie-stall or stanchion barns rather than free-stall facilities; and use of equipment to handle manure and subsequently handle feed. The adjusted population-attributable risk for these variables was 71, 43, 53, and 31%, respectively, and 99% overall, indicating that these variables had considerable effect on winter dysentery outbreaks.

Pathogen risk factors

Coronaviruses are divided into at least three antigenic groups, and antigenic cross-reactivity exists within an antigenic group. Bovine coronavirus, mouse hepatitis virus, murine enteric coronavirus, rat coronavirus, human coronavirus, porcine hemagglutinating encephalomyelitis virus belong to the same group. Bovine coronavirus is an important cause of neonatal calf diarrhea, and winter dysentery. BCV also possesses tropism for the respiratory tract of young cattle.

Some BCV strains isolated from the respiratory tract of cattle had different biological, antigenic, and genetic properties compared with enteric strains of the virus. Strains isolated from feedlot cattle and compared to those with the originally described Mebus prototype (from neonatal diarrheic calves) reveal that the respiratory strains of BCV may differ genetically from the classical calf enteric and adult winter dysentery strains.

Cross-protection studies between respiratory and calf diarrhea and winter dysentery coronavirus strains in calves have been examined using RT-PCR and nested PCR for their detection. Calves inoculated with bovine respiratory coronavirus (BRCV), calf diarrhea coronavirus (CD), winter dysentery (WD) coronavirus strains of BCV and the challenged 3 to 4 weeks later with either BRCV, CD, or WD strains of BCV developed diarrhea, then recovered and were protected from BCV-associated diarrhea after challenge exposure with either homologous or heterologous BCV strains. Nasal and fecal shedding of BCV, which were detectable only by nested PCR, after challenge exposure confirmed field and experimental data documenting reinfection of the respiratory and enteric tracts of cattle, indicating that in closed herds, respiratory or enteric tract infections may constitute a source of BCV transmission to cows or young calves. The biological, serological and genome properties of cytopathogenic RBCV strains isolated in Quebec and Ontario, Canada, have been compared to the original Mebus strain. RBCV strains have also been compared to previously characterized enteric bovine coronavirus strains in order to identify specific strain markers which should be considered for diagnosis and development of vaccines.

**PART 2 SPECIAL MEDICINE**

**Chapter 21: Diseases associated with viruses and Chlamydia**

103–105°F may precede the onset of diarrhea but when clinical signs are evident, the temperature is usually normal. There is a marked fall in milk yield which lasts for up to 1 week, anorexia of short duration, and some loss of body condition. The feces are liquid and homogeneous without much odor, and with no mucous or epithelial shred; the color is dark green to almost black. Feces are often passed with little warning and considerable velocity. A nasolacrimal discharge and cough may precede or accompany the epidemic. The frequency of coughing may be higher in those herds which have not experienced a more recent outbreak. In most animals the course is short and the feces return to normal consistency in 2–3 d. In occasional cases the syndrome is more severe, dehydration and weakness are apparent, and dysentery – either with feces flecked with blood or the passage of whole blood – occurs. The disease in the herd usually subsides in 1–2 weeks but in some cases production may not return to normal for several weeks or a few months.

In feedlot cattle, 6 to 9 months of age, the disease has been characterized by an acute onset of diarrhea with high morbidity and low mortality, dyspnea, coughing, and nasal discharge, and high body temperature (40 to 41°C in most severe cases). The diarrhea is characterized by fluid dark (brown-black) feces sometimes containing frank blood.

**Sheep**

Diarrhea and unthriftiness in groups of sheep have been associated with the virus but no published information is available.

**CLINICAL PATHOLOGY**

The laboratory diagnosis is dependent on detection of the virus in feces and serology. Fecal and blood samples should be submitted from both affected and normal cows.

**Detection of virus**

Fecal samples can be examined for the presence of bovine coronavirus using the ELISA test and by electron microscopy for viral particles. For routine purposes, direct electron microscopy viral identification and/or ELISA is sufficient. This can be complemented by protein A gold immune electron microscopy because of its high sensitivity and specificity in the detection of viral particles. A reverse transcriptase PCR (RT-PCR) can be used to detect the BCV in the feces of experimentally inoculated cattle. The 1-step RT-PCR and nested PCR assays were highly sensitive to detect BCV in nasal and fecal specimens and are useful for the etiological diagnosis of BCV in calves and adult cows.
Serology
In addition to detection of the virus in feces, an increase in the antibody titer to coronavirus based on acute and convalescent sera collected 8 weeks apart is supportive evidence that the virus is the causative agent. Attempts at diagnosing these infections serologically are often problematic because in adult cattle high BCV-specific IgG levels are often encountered in the acute samples, presumably due to reinfections with the virus, obscuring the detection of a possible increase in titer in paired samples. In addition, adult cattle are usually seropositive and maternal antibodies frequently obliterate the detection of infection in calves. There is a need for serologic tests that do not require the cumbersome and expensive paired samples necessary for an IgG based diagnosis.

A capture ELISA test for BCV-specific IgA and IgM in milk and sera has been developed and is useful for discriminating between primary infection and reinfection. In adult cattle, testing of paired serum samples using the antibody-capture ELISA may be a better indicator of recent BCV exposure than testing of serum samples with virus neutralizing assays. Antigen–antibody binding in feces may interfere with results of the antigen-capture ELISA for BCV.

Necropsy findings
In the rare fatalities available for necropsy, there is severe hemorrhage and hyperemia of the colonic and cecal mucosa. Frank blood may be present in the lumen of the large intestine. Microscopically there is widespread necrosis and degeneration of the epithelium of the large bowel. Similar but less severe gross and microscopic changes have been observed in experimentally infected cattle.

Samples for confirmation of diagnosis
- Histology – formalin-fixed cecum, colon (LM, IHC).
- Virology – colonic content (EM, ELISA), colon (FAT).

Differential diagnosis
Winter dysentery must be differentiated from:
- BVD/MD affects cattle 8–24 months of age in small outbreaks. Erosions of the oral cavity are present and the diarrhea and systemic effects are much more severe. The more recently recognized Type II BVD affects cattle of all ages including adult cattle and is a severe, highly fatal disease.
- Coccidiosis affects cattle from 3–12 months of age and is characterized by frank blood in the feces and tenesmus, and the fecal sample is usually diagnostic.
- Enteric salmonellosis is a severe toxemic enteritis with diarrhea and dysentery, fibrinous casts in the feces, a high fever, severe depression and rapid death. Culture of the feces is important.
- Group B rotavirus. Rare cases of diarrhea in mature lactating dairy cows associated with Group B rotavirus have been described. The onset of diarrhea is sudden, milk production decreases, the feces are liquid, and recovery occurred in 3 to 5 days.
- Respiratory tract infections. The clinical findings of dyspnea, nasal discharge, coughing, and fever associated with the bovine respiratory coronavirus must be differentiated from acute undifferentiated bovine respiratory tract disease.

Treatment
Treatment is of doubtful value because affected cattle usually respond spontaneously in 24–36 h. Occasionally dehydration will become severe and is best treated with fluids and balanced electrolytes as indicated.

Control
Management
Because of the explosive nature of the disease and the lack of information on possible precipitating causes, effective control measures cannot be recommended. Every effort must be made to avoid the spread of infection on inanimate objects such as boots, feeding utensils and bedding, but even the greatest care does not appear to prevent the spread of the disease within a herd.

Vaccination
Some preliminary studies have tested the potency of bovine coronavirus vaccine to induce serum antibodies but randomized controlled trials to test the efficacy of the vaccine have not been done.

References

Etiology
Bluetongue virus (BTV) is an arthropod-borne Orbivirus in the family Reoviridae. Within the BTV serogroup there are at least 24 serotypes of BTV worldwide. There is considerable genetic variability within the serogroup. This arises by genetic drift of individual gene segments as well as by reassortment of gene segments when nomenclature or the vectors are infected with more than one strain. There is also debate of the biological validity of the classification of B TV into strict types. All serotypes do not exist in any one infected area.

Epidemiology
Occurrence
Bluetongue virus infects domestic livestock populations in all tropical and subtropical countries and occurs on the continents of Africa, Asia, North America, South America, Australia and several islands in the tropics and subtropics, primarily between latitudes 40°N and 35°S. Incusive disease has occurred in Portugal, Spain and Greece but until very recently bluetongue was not considered an endemic
infection in Europe. However, in an epidemic beginning in 1998, and persisting to date (2005), five serotypes have spread across and persisted in 12 countries in southern Europe occurring 800 km further north than ever previously recorded. This persistence indicates over-wintering of these infections in these new regions and is believed the result of climate change from global warming.

The distribution and intensity of infection in regions of the continents is determined by the climate, geography and altitude, as they affect the occurrence and activity of the *Culicoides* vectors, and by the presence of susceptible mammalian hosts. There is a gradation from continuous BTV activity in tropical areas to absence of virus transmission in colder areas. In large countries that span different latitudes, such as the United States and Australia, there are areas that are free of infection.

In endemic areas, the infection is always present but clinical disease of the indigenous species is unusual. It can occur with new BTV strains and when non-indigenous susceptible species are introduced to the area.

Epidemic zones also exist, where infection and clinical disease occur every few years. Infection in these areas is highly focal and outbreaks occur when climatic conditions allow the vector to spread beyond its usual boundaries and to infect susceptible ruminants.

Incursive disease can occur in regions which do not normally experience infection and may occur when the virus is introduced by windborne movement of infected *Culicoides* with subsequent insect breeding in the summer before ‘die out’ in the autumn and winter. This method of spread is believed to have been the genesis of several serious outbreaks of bluetongue in countries normally free of the disease and of the outbreaks in Portugal in 1956, in Cyprus in 1977, in Turkey and Greece in 1979–1980 and in Israel in 1960–1980. Polymerase chain reaction-based procedures can be used to determine the serotypic and geographic origin of infection with BTV.

In the United States, the prevalence of seropositive cattle varies from high in the southern and western states to low in the northern states, especially the northeastern states. In the northwest region, there are epidemics of infection in the summer and fall every few years, associated with movement of infected vectors from the south. Canada is free of infection except for periodic incursions into the Okanagan Valley in British Columbia from windborne infected *Culicoides* from south of the border. In Australia, there has been a sequential introduction of bluetongue serotypes from Indonesia by windborne *Culicoides* ssp. but endemic infection is limited to northern cattle areas with extension down the east coast.

**Host occurrence**

Infection occurs in a number of animals but significant disease occurs only in sheep. Cattle are the major reservoir host for sheep. Under natural conditions infection occurs in sheep and cattle, but it is also recorded in elk, white-tailed deer, pronghorn antelope, camels and other wild ruminants. Natural infection rarely occurs in goats but the infection can be transmitted experimentally.

**Method of transmission**

The disease is not contagious and is transmitted biologically by certain species of *Culicoides*. There are over 1400 species of *Culicoides* worldwide but only a limited number have been associated with BTV. Female *Culicoides* feed on cattle and horses and also sheep, deer, and goats, requiring at least one blood meal for the completion of the ovarian cycle. They feed nocturnally on animals in open pens and fields and the optimal temperatures for activity lie between 13°C and 35°C.

Virus in ingested blood infects cells of the midgut by a receptor-mediated process, replicates and subsequently is released to the salivary gland. Once infected, they are infected for life—a period of several weeks. They may feed twice or more and on different hosts, and achieve transmission at successive feedings. After feeding on a viremic animal, BTV is usually less than 10 days and on different hosts, and achieve their greatest transmission potential 6–14 d after feeding on a viremic animal. BTV is maintained in nature by alternating cycles of infection between the midge and ruminant species. In many areas the disease is seasonal because *Culicoides* are killed by the first hard frost.

*Culicoides* breed in damp, wet areas including streams, irrigation channels, muddy areas and feral runoff areas around farms, and habitats for them exist on the majority of farm environments. Species that are cattle associated, such as *C. brevitarsis*, breed in cattle dung. The generation time in the summer is about 14 d. Different species have different geographic occurrence and their distribution in a country is determined by climatic factors and the presence of a preferred host.

*Culicoides* species

In the United States, *C. variipennis* var *sonorensis* is the vector except in the southeast where it is *C. insignis*. This species and *C. psilicus*, *C. insignis*, *C. psilicus* and *C. filarifer* are also important in transmission in the Caribbean and Central and South America. There are other subtypes of *C. variipennis* in the United States which have different distributions to *C. variipennis* var *sonorensis*. In Africa, *C. micola* (*pallidipennis*) is a major vector and in the Middle East and Asia *C. felis*, *C. micola*, *C. oboletus*, *C. nudipalpis* and *C. orientalis*. In Australia, *C. wadai*, *C. actoni*, *C. brevitarsis*, *C. peregrinus*, *C. oxystoma*, *C. brevipalpis* and *C. fulus* are vectors or potential vectors. They have different distribution in the country which oscillates, depending on climate. *C. brevitarsis*, *C. brevipalpis* and *C. wadai* are obligate parasites of cattle (dung breeders), but the others can complete their lifecycle in the absence of cattle. *C. brevitarsis* is the most extensively dispersed vector. *C. micola* has been involved in the recent expansion of bluetongue in southern Europe, but *C. oboletus* and *C. pulicaris* have been implicated as new vectors in these regions.

Other vectors

Other vectors may transmit the disease mechanically but are unlikely to be of major significance in disease epizootics. The argasid tick *Ornithodoros coriaceus* has been shown experimentally to be capable of transmitting the virus and be a potential vector. The sheep ked (*Melophagus ovinus*) ingests the virus when sucking the blood of infected sheep and can transmit the infection in a mechanical manner. Mosquitoes may play a role in transmission and *Aedes lineatopennis* and *Anopheles vagus* have been suspect.

Over-wintering

The life span of an adult culicoides is usually less than 10 days and at the most a few weeks. Cold winters kill virtually all of the adult vectors and there can be no transmission during these cold periods. Despite this there is an annual recrudescence of bluetongue in several temperate areas. The reason for the persistence of the infection from season to season is not fully understood. There is the possibility of the virus over-wintering in the insect vector but there is little evidence in support of this. *Culicoides* survive winter periods as larvae but there is no evidence of transovarial transmission of BTV in these insects.

With infected animals bluetongue viruses can be isolated after initial infection for only a short period of time in infected sheep and only slightly longer in cattle. Infection of *Culicoides sonorensis* that were allowed to feed on infected animals occurred for only 11 days after initial infection in sheep and 49 days following infection of cattle although bluetongue virus nucleic acid can be detected for longer periods. An analysis, in 2001, of published data indicated that the duration of viremia in cattle ceased by 63 days after...
infection in adult cattle and a slightly longer period in infected colostrum-deprived calves. Infection, as detected by routine isolation if virus, can also persist in wild ruminants.

However, none of these periods adequately explain the recrudescence and apparent over-wintering of infection in some areas. It has been recently shown that infectious BTV can be recovered from ovine skin biopsies for more than 9 weeks after infection and it is postulated that infection can be covertly present in seropositive and aviremic ruminants as a result of a persistent infection established in γδ T-cells. This covert but persistent infection is believed to allow perpetuation of BTV through the winter. It is suggested that the occurrence of new vectors in the following spring with biting activity results in skin inflammation with recruitment of inflammatory cells including γδ T-cells and that interaction of these infected cells with skin fibroblasts results in a conversion of a persistent infection of the γδ T-cells to a productive lytic infection that allows subsequent infection of biting vectors.

Veneral transmission
Bluetongue virus has been found in the semen of infected bulls during the initial viremic period, and infection has been transmitted through bull semen to susceptible cows, but it is unlikely that this is a significant mechanism of transmission. Transplanted embryos from infected services are free of the virus and this is regarded as a minimal risk technique for obtaining offspring from cattle and sheep in infected areas.

Persistent infection
Persistent infection in immunotolerant animals following in utero infection, once thought to be of importance, is now believed not to occur.

Pathogen and vector risk factors
The geographical distribution of bluetongue serotypes varies and is changing with time. There are differences in virulence between serotypes and between strains within serotypes and virulence is also related to virus dose and dependent on vector species, distribution and competence. Different Culicoides species vary in susceptibility to infection and some known vectors are resistant to infection with some serotypes, which in part explains regional differences in serotype occurrence. Different Culicoides species have different host preferences and some have a distinct preference for cattle and little host preference for sheep.

Climate
Climate is a major risk factor as culicoids require warmth and moisture for breeding and calm, warm, humid weather for feeding. A cold winter or a dry summer can markedly reduce vector numbers and risk for disease. Moisture may be in the form of rivers and streams or irrigation but rainfall is the predominant influence and rainfall in the preceding months is a major determinant of infection.

Precipitation affects the size and persistence of breeding sites and the availability of humid microhabitats to allow shelter from desiccation during hot summer and autumn periods. Optimal temperature is also essential, and in endemic areas temperatures for survival of the adults and larve require temperatures sustained above a mean of 12.5°C for the cooler months and temperatures in the range of 18 to 30°C in the summer and autumn for optimum recruitment to adults and for optimal adult activity. Temperature also affects the rate of virus production in culicoids. Geographic information systems (GIS) can be used to predict area risk.

Serotype occurrence
Genetic studies indicate that BTV tends to exist in discrete, stable ecosystems and that BTV serotypes that circulate in one region of the world are largely different from those in other regions. In the United States, five serotypes – 2, 10, 11, 13, and 17 – have been isolated. Serotype 2 is a relatively recent isolate and is restricted to the habitat of C. insignis, but the latter four are endemic throughout much of the south and west. Serotype 13 is probably a reassortment virus with a gene segment derived from a vaccine virus parent and other reassortments between live vaccine viruses and wild-type viruses are a concern for the emergence of virus types that could posses enhanced virulence characteristics or novel antigens properties. In the Caribbean Region and South and Central America, serotypes 1-4, 6, 8, 12, 14, and 17 are reported. In Australia, eight serotypes – 1, 3, 9, 15, 16, 20, 21, and 23 – have been isolated. Six of these (3, 9, 15, 16, 20, and 23) have only been found in the north of the Northern Territory, while two serotypes (1 and 21) are widely distributed across the northern and eastern coast of Australia. The introduction appears to have been sequential and five have been introduced since 1981. The virus has been isolated from infected Culicoides and small animals and although there is serological evidence of infection in Queensland and New South Wales, there has been no clinical disease. In Africa, serotypes 1, 16, 18, 19, and 24 are the major serotypes isolated and in Asia, serotypes 1, 4, 7, 9, 10, 12, 16, 17, 20, 21, and 23 are associated with disease in the current expansion in southern Europe.

The bluetongue viruses are stable and resistant to decomposition and to some standard virucidal agents, including sodium carbonate. They are sensitive to acid, inactivated below pH 6.0, and susceptible to 3% sodium hydroxide solution and organic iodides.

Host risk factors
Cattle
Cattle are the reservoir and amplifying host and have a high titer viremia. Cattle appear to be much more attractive to Culicoides spp. and this may enhance the importance of cattle as carriers. A critical density of cattle in a region may be required to sustain bluetongue in regions where the Culicoides vector is strongly associated.

Bos taurus breeds are more likely to be seropositive than Bos indicus and bulls have a greater risk for infection than females or castrated males. Seroprevalence increases with age, probably a reflection of increased duration of exposure.

Sheep
All breeds of sheep are susceptible but to varying degrees. Merinos and British breeds are more susceptible than native African sheep. There are also differences in age susceptibility to clinical disease which, inexplicably, vary with different outbreaks. With Australian serotypes, disease occurs only in sheep 3 years of age or older. Exposure to solar radiation can increase the severity of the disease, as can excessive droving, shearing, poor nutrition and other forms of stress.

Morbidity and case fatality
When the disease occurs in a flock for the first time the incidence of clinical disease may reach 50-75% and the mortality 20-50%. Outbreaks in Cyprus and Spain were accompanied by mortality rates of 70% in affected flocks but most outbreaks result in much lower mortality. Mortality rates of 2-30% are reported under field conditions in South Africa and from 0-14% in field outbreaks in the United States. High mortality can occur when a new strain of BTV emerges in an area.

Immunity to BTV tends to be strain specific and in epizootics, more than one strain may be introduced into an area. Infections caused by different serotypes may follow one another in quick succession in a sheep population. The serotypes vary widely in their virulence with a corresponding variation in the severity of the disease produced. However, sequential infection with more than one type of BTV results in the development of heterotypic antibody and may result in protection...
against heterologous serotypes not previously encountered.

Experimental reproduction
Infection is readily produced by experimental infection of sheep and cattle but it is common for the clinical presentation of the experimental disease to be very mild despite the fact that the isolate might have been associated with severe disease in the field. In many cases experimental infection produces viremia, fever, leukopenia and an antibody response but the localized, identifying lesions are often minimal, with erythema of the coronary bands as the only visible abnormality in some cases.

Fetal infection
Congenital defects of the nervous system of lambs occur when pregnant ewes are vaccinated with attenuated vaccine virus, and when calves and lambs are inoculated experimentally before midgestation, but occur rarely with natural infection. Unadapted virus does not readily cross the placenta. Experimental inoculation of pregnant ewes is more likely to lead to fetal death with a generalized hepatic necrosis and suppressed hepatic hematopoiesis. Infection of the ewe in mid-pregnancy can result in infection of the lamb which is unaffected and born normally, but viremic so that it may remain as a source of infection for a further 2 months. However, such lambs are not expected to have a major role in the spread of the disease.

The location and the nature of the lesions in the lambs of ewes injected with attenuated vaccine virus is related to the level of maturation and migration of nerve cells at the time infection occurs. The degenerative nature of the lesions results from the presence of immature neural cells with enhanced viral susceptibility combined with an inability to mobilize an effective immunological response. In older fetuses, a typical inflammatory response develops and there is also a generalized retardation of growth and lymphoreticular activity.

Experimental inoculation of cows at 60-120 d of pregnancy with virulent viruses can cause congenital defects, including excessive gingival tissue, agnathia (tilltted mandible), arthrogryposis, ataxia and head pressing. Hydranephrocephaly or porencephaly may also be a sequel to infection with more virulent strains. The severity of the brain lesions decreases with increasing fetal age and infection at 243 d results in a mild encephalitis and the premature birth of calves which are still viremic but poorly viable.

Economic importance
Mortality varies with the serotype but can be significant and it is estimated that the incursion of the disease in Europe since 1998 has caused has death of over 1 million sheep. However, production loss is also of great importance. Adults either lose their fleece from a break in the growth of the staple or develop a weakness (tender wool) that causes breaks in processing and markedly reduces the value of the fleece. Pregnant ewes commonly abort. There is a severe loss of condition and convalescence is prolonged, particularly in lambs. The loss from clinical disease and from reduced wool quality and suboptimal production following infection in sheep are significant.

A further major indirect cost of the disease is the restriction in international trade. The severe disease that occurred in the outbreaks in Cyprus and the Iberian peninsula in the 1940s and 1950s resulted in bluetongue being placed on list A of veterinary diseases by the Office International des Epizooties (OIE). As a result there are restrictions on the international movement of cattle and sheep and their products from countries that have this infection to those that do not. The validity of these restrictions imposed by countries where bluetongue is unlikely to transmit is questionable. It is estimated that the United States has an annual loss of $144 million because of the inability to trade with BTV-free countries.

Movement restrictions within an affected country, even though having limited scientific reason for imposition with bluetongue, can have a significant economic effect on a country's tourist-related income. In the year 2005 movement restrictions for cattle in Spain threaten the quality of bullfights and functions such as the running of the bulls in the Pamplona festival.

PATHOGENESIS
Sheep
The pathology of bluetongue can be attributed to vascular endothelial damage resulting in changes to capillary permeability and fragility, with subsequent disseminated intravascular coagulation and necrosis of tissues supplied by damaged capillaries. These changes result in edema, congestion, hemorrhage, inflammation and necrosis. Following infection into the skin, there is replication in the local draining lymph node and dissemination in mononuclear cells to secondary sites of replication in lymphoid tissue and lung. Viremia is detectable by day 3 and peak viremia, associated with fever and leukopenia, usually occurs 6-7 d after infection. Circulating virus concentrations subsequently fall with the appearance of circulating interferon and specific neutralizing antibodies. With the viremia, there is localization of the virus in vascular endothelium which causes endothelial cell degeneration and necrosis with thrombosis and hemorrhage. There is also the development of a hemorrhagic diathesis and coagulation changes consistent with disseminated intravascular coagulation. The distribution of the lesions is believed to be influenced by mechanical stress and the lower temperatures of these areas in relation to the rest of the body.

Cattle and wild ruminants
With infection in cattle and wild ruminants, infection of endothelial cells is minimal. The viremia in cattle is highly cell associated, particularly with erythrocytes and platelets. Although the virus does not replicate in the erythrocytes, it is protected from circulating neutralizing antibody and infected erythrocytes are likely to circulate for their lifespan. BTV antigen can be detected in erythrocytes of cattle 140 d after infection. The severe clinical disease that occurs in only a few infected cattle is possibly a type 1 hypersensitivity reaction dependent upon virus-specific IgE from repeated exposure.

The presence of the bluetongue virus in the semen of bulls is accompanied by structural abnormalities of the spermatozoa and by the presence of virus particles in them.

CLINICAL FINDINGS
Sheep
Naturally occurring, florid bluetongue in sheep has the following clinical characteristics. After an incubation period of less than a week, a severe febrile reaction with a maximum temperature of 40.5-41°C (105-106°F) is usual, although afebrile cases may occur. The fever continues for 5 or 6 d. About 48 h after the temperature rise, nasal discharge and salivation, with reddening of the buccal and nasal mucosa, are apparent. The nasal discharge is mucopurulent and often blood stained and the saliva is frothy. Swelling and edema of the lips, gums, dental pad and tongue occur and there may be involuntary movement of the lips. Excoriation of the buccal mucosa follows, the saliva becomes blood stained and the mouth has an offensive odor.

Lenticular, necrotic ulcers develop, particularly on the lateral aspects of the tongue, which may be swollen and purple in color, but more commonly is not. Hyperemia and ulceration are also common at the commissures of the lips, on the buccal papillae and around the anus and vulva. Swallowing is often difficult for the animal. Respiration is obstructed and stertorous and is increased in rate up to 100/min. Diarrhea and dysentery may occur.
Foot lesions, including laminitis and coronitis, and manifested by lameness and recumbency, appear only in some animals, usually when the mouth lesions begin to heal. The appearance of a dark red to purple band in the skin just above the coronet, due to coronitis, is an important diagnostic sign. Wryneck, with twisting of the head and neck to one side, occurs in a few cases, appearing suddenly around day 12. This is apparently due to the direct action of the virus on muscle tissue as is the pronounced muscle stiffness and weakness which is severe enough to prevent eating. There is a marked, rapid loss of condition. There is facial swelling with extensive swelling and drooping of the ears and hyperemia of the non-wooled skin may be present. Some affected sheep show severe conjunctivitis, accompanied by profuse lacrimation. A break occurs in the staple of the fleece. Vomiting and secondary aspiration pneumonia may also occur. Death in most fatal cases occurs about 6 days after the appearance of signs.

In animals that recover, there is a long convalescence and a return to normal may take several months. Partial or complete loss of the fleece is common and causes great financial loss for the farmer. Other signs during convalescence include separation or cracking of the hooves and wrinkling and cracking of the skin around the lips and muzzle. Although the subsequent birth of lambs with porencephaly and cerebral necrosis is usually recorded after vaccination with attenuated virus, it also occurs rarely after natural infections.

In sheep in enzootic areas, the disease is much less severe and often inapparent. Two syndromes occur: (i) an abortive form in which the febrile reaction is not followed by local lesions and (ii) a subacute type in which the local lesions are minimal, but emaciation, weakness and extended convalescence are severe. A similar syndrome occurs in lambs which become infected when colostral immunity is on the wane.

Cattle
Most infections are inapparent, although a few animals may develop a clinical syndrome not unlike that seen in severely affected sheep. Clinical signs which have been recorded include:
- Fever (40–41°C, 104–106°F)
- Stiffness and laminitis in all four limbs
- Excessive salivation
- Edema of the lips
- Inappetence
- Nasal discharge
- Fetid breath.

Many affected cattle also have ulcerative lesions on the tongue, lips, dental pad, and muzzle. A severe coronitis, sometimes with sloughing of the hoof, may occur. Some cows have photodermatitis and lesions on the teats. Serosanguineous exudate may appear in the nostrils and a discharge from the eyes. Contraction of the infection during early pregnancy may cause abortion or congenital deformities including hydranencephaly, microcephaly, curvature of the limbs, blindness and deformity of the jaw.

Goats
Infected goats show very little clinically. There is a mild to moderate fever, and hyperemia of the mucosae and conjunctiva. BTV infections in deer produce an acute disease that is clinically and pathologically identical to epizootic hemorrhagic disease of deer and characterized by multiple hemorrhages throughout the body.

CLINICAL PATHOLOGY
There is a fall in packed cell volume and an initial leukopenia followed by a leukocytosis. In severe disease there is a marked leukopenia, due largely to lymphopenia. Infected cattle show a similar leukopenia. The skeletal myopathy which occurs in this disease is reflected by a rise in creatinine phosphokinase.

Specific diagnosis is either by isolation of the viral virus, detection of viral antigen or nucleic acid, or detection of specific antibodies in serum. Serological assays can detect prior exposure to BTV but cannot establish if the animal is viremic, which is currently still important for movement decisions concerning cattle.

Virus isolation
Virus isolation commonly is carried out by inoculation of chick embryos. The virus can be isolated from blood during the febrile period and it, or detection of viral nucleic acid, is the most reliable confirmation of BTV infection because there are difficulties with the interpretation of serological test results. However, traditional isolation methods require 2–4 weeks.

Less commonly, diagnosis is by inoculation of blood into susceptible sheep. A positive test depends on the appearance of diagnostic clinical signs and resistance to subsequent challenge with the blue-tongue virus, or a significant increase in virus-neutralizing antibodies in the recipient sheep.

Detection of antigen or nucleic acid
Immunohistochemical tests including immunofluorescence, immunoperoxidase and immunoelectron microscopic techniques using monoclonal antibody can be used for rapid sensitive and specific detection of antigen. In situ nucleic acid hybridization and PCR can be used for detection of the virus and have the advantage of speed over tissue culture virus isolation and can also differentiate between wild-type isolates and vaccine strains. Tests that detect viral RNA do not necessarily indicate that an infectious virus is still present.

Serological tests
A number of serological tests are available based on the detection of group-reactive antibody or serotype-specific antibody. Bluetongue diagnosis by serology is imprecise, unless a rising titer is demonstrated in acute and convalescent serum samples. The commonly available tests include complement fixation, the AGID, a number of different ELISA tests and virus neutralization. In most laboratories the complement fixation test has been replaced by the AGID test. The AGID test is easy to perform and inexpensive. Antibody appears 5–15 days after infection and persists for 2 or more years. The test is relatively insensitive and detects cross-reacting antibodies to other orbiviruses. Also, in epizootics a significant proportion of antibody-negative animals may be viremic.

There are a number of ELISA tests that have been developed using group-specific monoclonal antibodies and that have been suggested as alternates to the AGID for routine diagnosis and international trade. The competitive ELISA appears more sensitive than most and is highly specific and may replace the AGID test as the preferred test for serological diagnosis of bluetongue.

NECROPSY FINDINGS
The mucosal and skin lesions have already been described. Other consistent lesions include generalized edema, hyperemia and hemorrhage and necrosis of skeletal and cardiac muscles. There is a most distinctive hemorrhage at the base of the pulmonary artery. Animals with damage to esophageal or pharyngeal musculature may have lung consolidation due to aspiration pneumonia. Hyperemia and edema of the abomasal mucosa are sometimes accompanied by ecchymoses and ulceration. Microscopically there is thrombosis and widespread microvascular damage leading to myodegeneration and necrosis. Abscessed bovine fetuses should be examined for evidence of hydranencephaly or porencephaly. As previously discussed, there are numerous tests available to confirm the presence of BTV in blood and tissue samples.

SAMPLES FOR CONFIRMATION OF DIAGNOSIS
- Histology – fixed oral and mucocutaneous lesions, abomasum, pulmonary artery, skeletal muscle from a variety of sites, left ventricular
papillary muscle. Brain from aborted fetus. (LM, IHC)

- **Virology** – chilled lung, spleen. CNS tissues, thoracic fluid from aborted fetus (ISO, PCR, in situ HYBRID, ELISA, etc.)

### Differential Diagnosis

- Foot-and-mouth disease
- Epizootic hemorrhagic disease
- Contagious ecthyma
- Sheep pox

### Treatment

Local irrigations with mild disinfectant solutions may afford some relief. Affected sheep should be housed and protected from weather, particularly hot sun, and fluid and electrolyte therapy and treatment to control secondary infection may be desirable.

### Control

**Reduction of infection through vector abatement**

Attempts to control bluetongue through a reduction of infection consist of reducing the risk of exposure to infected Culicoides and reduction in Culicoides numbers. Neither are particularly effective.

Reducing the risk of exposure is attempted by spraying cattle and sheep with repellents and insecticides and housing sheep at night. Biweekly application of permethrin was found not to be effective in preventing infection.

During transmission periods avoidance of low, marshy areas or moving sheep to higher altitudes may reduce risk. Because of the preference of some Culicoides for cattle as a host, cattle have been run in close proximity to sheep to act as vector decoys. Widespread spraying for Culicoides control is not usually practical and has only a short-term effect.

There is a high mortality in Culicoides that fed on cattle that have been treated with a standard anthelmintic dose of ivermectin and also a larvicidal effect in manure passed for the next 28 d for Culicoides that breed in dung.

### Vaccination

Vaccination is the only satisfactory control procedure once the disease has been introduced into an area. Vaccination will not prevent or eliminate infection but it is successful in keeping losses to a very low level provided immunity to all local strains of the virus is attained. Current vaccines are usually polyvalent attenuated virus vaccines and are in use in South Africa and Israel and available in other countries. These vaccines have been used in South Africa for more than 50 years and they are known to induce effective and long lasting immunity. Currently they are produced in cell culture and freeze-dried. The present Ondersteipoort Bluetongue Vaccine comprises three bottles (Vaccines A, B, and C) and includes the following serotypes of BTV:

- Bottle A: BTV serotypes 1, 4, 6, 12, and 14
- Bottle B: BTV serotypes 3, 8, 9, 10, and 11
- Bottle C: BTV serotypes 2, 5, 7, 13, and 19

The three bluetongue vaccines are administered separately at 3-week intervals.

Reactions to vaccination are slight but ewes should not be vaccinated within 3 weeks of mating as anestrus often results. **Annual revaccination** 1 month before the expected occurrence of the disease is recommended. Immunity is present 10 d after vaccination so that early vaccination during an outbreak may substantially reduce losses. Lambs from immune mothers may be able to neutralize the attenuated virus and fail to be immunized, whereas field strains may overcome their passive immunity. In enzootic areas, it may therefore be necessary to postpone lambing until major danger from the disease is passed and lambs should not be vaccinated until 2 weeks after weaning. Rams should be vaccinated before mating time.

Live attenuated vaccines should not be used in pregnant ewes because of the risk of deformity in the lambs or embryonic death. The danger period is between the 4th and 8th weeks of pregnancy with the greatest incidence of deformities occurring when vaccination is carried out in ewes pregnant for 5–6 weeks. The incidence of deformities may be as high as 13%, with an average of 5%. Abortions do not occur although some lambs are stillborn.

The preparation and use of attenuated vaccines against BTV is problematic. The neutralizing epitopes are highly conserved on some serotypes but they are highly plastic on others. It is therefore necessary to continually monitor the identity and prevalence of the serotypes that need to be in the vaccine.

There are also concerns for the use of live vaccines to control insect-borne diseases because of the risk of the vaccine strain being transmitted, of being exalted in virulence by passage, and of recombinants resulting in the development of new virus strains with unwanted characteristics. There is evidence for the emergence of a reassortment strain from a vaccine virus in the United States and suspicion of occurrence elsewhere. However, living vaccines are used for practical reasons, including the fact that inactivated vaccines do not provide protection against infection. The difficulty in obtaining safe vaccines may be overcome by the use of recombinant DNA technologies. There is also good reason to suggest that cattle should be a major target of vaccination for bluetongue control.

### International Movement of Livestock

Countries that are free of BTV infection have traditionally erected barriers to avoid its introduction by **prohibiting** the importation of any ruminant animals from countries where the disease occurs. Others have less severe restrictions and several procedures aimed at permitting limited movement are in force; their stringency varies with the importing country. Some countries only require a negative serological test or series of tests prior to movement. Others require a negative test in conjunction with a period of quarantine. The introduction of bovine **semen** from low-risk areas after suitable tests of donors and a prolonged storage period is accepted by most countries. Most countries allow the importation of embryos.

A more enlightened understanding of the epidemiology of bluetongue will probably result in a re-evaluation of these requirements in the future including regionalization within a country to allow exports from areas where there is no prevalence or transmission.

Viral diseases characterized by alimentary tract signs

**EPIZOOTIC HEMORRHAGIC DISEASE**

Epizootic hemorrhagic disease virus (EHDV) is a serogroup of *Orbivirus* closely related to bluetongue virus. There are at least 10 serotypes and some have antigenic relations with serotypes of bluetongue virus.1 The serotypes infect deer and cattle naturally; sheep may be infected experimentally but not goats or pigs. In deer, the serotypes produce clinical disease. The pathogenesis of epizootic hemorrhagic disease is similar to that of bluetongue virus and infection of ruminants with either virus is characterized by extensive vascular injury, disseminated intravascular necrosis and tissue necrosis.2

The geographic occurrence of epizootic hemorrhagic disease viruses is similar to that of bluetongue virus. The virus, or serological evidence of infection, occurs on the North American, Australian, Asian and African continents.3 In North America, there are two serotypes (EHDV-1, EHDV-2) and infection occurs in all areas of the United States, except the northeast and the arid southwest, and in southern Canada. In Australia, five serotypes are identified, of which three are isolated from sentinel cattle in the north.4 Transmission is by species of *Culicoides* and some species of gnats and mosquitoes.3 There are also geographic differences in the severity of disease following EHDV infection with clinical disease in cattle being of rare occurrence in the United States but capable of causing outbreaks of disease in cattle in Asia.

**Infection in deer**

In North America, epizootic hemorrhagic disease is considered one of the most important diseases of deer, particularly of white-tailed deer (*Odocoileus virginianus*) but also mule deer (*O. hemionus*, and pronghorn antelope (*Antilocarpa americana*).5 There are areas of enzootic stability, where seroprevalence in deer is high but clinical disease rare, and areas with low seroprevalence where clinical disease is severe.6,7 All ages are susceptible, morbidity can be as high as 90% and mortality as high as 60% in some deer herds. The virus infects endothelial cells and the pathogenesis, clinical signs and postmortem lesions are similar to those of acute bluetongue in sheep with fever, hemorrhage and death.

**Infection in cattle**

Seroprevalence studies suggest that infection of cattle is common but clinical disease is very rare. An exception is infection with a genetically distinct strain of EHDV-2, which was initially associated with an epizootic of disease of cattle in Japan in 1959, called *Ibaraki disease*, and which resulted in 39 000 sick cattle and 4000 deaths.8 Disease with this agent was subsequently observed in other Asian countries. Clinically, the disease was characterized by fever, hyperemia and edema of the mucosa, a hemorrhages ulcerative stomatitis with laryngeal and pharyngeal paralysis salivation and dysphagia. At postmortem there were hemorrhages in the pharynx and esophagus and animals commonly died with aspiration pneumonia. Infection of pregnant cattle with Ibaraki virus can also result in abortion and stillbirths and currently this seems a more common clinical manifestation. There is evidence of genetic change in isolates from different outbreaks and the clinical manifestations of infection with different strains can vary.9,10

Occasional disease associated with infection with EHDV is recorded in cattle in the late summer in the United States and is also recorded in a recent outbreak on the island of Reunion.11 It is similar to bluetongue and manifest with fever, lameness, reddening and swelling of the oral mucosa with necrotic ulceration of the dental pad and behind the incisor teeth, cracking and sloughing of the skin of the muzzle and hyperemia of the skin of the teats and udder;2 Morbidity has ranged from 1–20%.

**Diagnosis** of infection is by virus isolation, nucleic acid identification and serology. AGID will detect antibody but will also detect cross-reacting antibodies with bluetongue. The c-ELISA is specific and sensitive.12

Viral diseases characterized by respiratory signs

**VIRAL INFECTIONS OF THE UPPER RESPIRATORY TRACT OF HORSES**

Viral respiratory tract disease is considered by veterinarians in the United States to be second only to colic among medical diseases in importance to the health and welfare of horses. The situation is likely similar in most developed countries and especially those in which equine influenza is endemic. Episodes of upper respiratory tract disease characterized by fever, nasal discharge and cough are common in horses, especially young animals and horses housed in groups in stables and barns. An estimated 17% of equine operations in the United States have one or more horses affected by upper respiratory disease each year, and 1.5% of horses develop the disease every 3 months. Upper respiratory disease is most common in spring and least common in winter. Strangles was an uncommon cause of disease, occurring in only three horses per 1000 per 3 months. Viral respiratory disease is approximately three times more common in horses less than 5 years of age. With the exception of *Streptococcus equi* and possibly *Mycoplasma* spp., the known causes of infectious upper respiratory disease of horses are viral and include: equine herpesvirus types 1, 2 and 4, equine influenza virus, equine rhinovirus types A and B (ERAV and ERBV), equine adenovirus, equine viral arteritis, and equine parainfluenza 3 virus. Equine Hendra virus and African horse sickness virus cause signs of severe respiratory disease. Both strangles and equine viral arteritis can be mild and lack outstanding clinical signs, thus closely resembling disease associated with other viral causes of upper respiratory tract disease. Therefore, differentiation among diseases associated with these agents based on clinical signs and epidemiological characteristics is difficult and definitive diagnosis is only achieved through serological or microbiological examination of blood or nasal discharge. **Isolation and identification** of a causative organism from nasopharyngeal swabs or airway washings of acutely affected horses provides a definitive diagnosis, although on occasion more than one potential pathogen may be isolated. Demonstration of **seroconversion** or a three- to four-fold increase in titer from serum samples collected during the acute and convalescent (usually 3 weeks after onset of clinical signs) phases of disease is persuasive evidence of infection. Immunofluorescence, enzyme-linked immunosorbent assay (ELISA) and polymerase chain reaction (PCR) tests may provide...
rapid diagnosis through detection of viral particles in nasal swabs and tissue specimens. The ability to determine the cause of an outbreak of upper respiratory disease in horses is enhanced by the use of multiple diagnostic tests and obtaining samples from more than one horse in an outbreak. However, definitive diagnosis of the cause of nasal discharge, cough, and fever is often not achieved.4 All the agents known to cause upper respiratory disease in horses are relatively sensitive to environmental influences, and spread of the agent is dependent on transmission from infected horses, either directly or on fomites. Introduction of an infected horse into a susceptible population of horses may result in an explosive outbreak of upper respiratory tract disease. Such events are common on stud fums and in racing stables, where relatively closed bands of horses are maintained for much of the year. The movement of horses over long distances may facilitate the introduction of pathogens to which the local population of horses is naive.

The opposite situation occurs when young horses are introduced into larger bands of mixed aged animals, such as happens in racing stables or barns of pleasure horses. The younger, possibly naive, horse is then exposed to endemic pathogens to which the resident horses have developed resistance. Young horses are at particular risk of developing infectious disease of the upper respiratory tract. The diseases are usually a problem only in yearlings and 2-year-olds; young foals acquire a passive immunity from the dam and adults have acquired a permanent immunity through exposure or vaccination. In a horse population it is the average age and the mix of ages which largely determine its herd resistance, and when 30–40% of that population has not previously been exposed to infection then major outbreaks are likely. All of the diseases are transmitted by droplet infection, and over long distances so that limitation of their spread is possible only by rigid isolation and intensive sanitary precautions, and even the best protected studs are likely to be invaded from time to time.

Equine rhinitis virus (ERV) There are two, and possibly three, strains of equine rhinitis virus, (ERV, ERB) that infect horses. ERV is more closely related to foot-and-mouth disease than to other picornaviruses. Almost all the information available on ERV infection of horses is for ERV. The virus has been well characterized. Serologic evidence of infection with ERV is present in 50–100% of horses.9,10 The virus is present in nasal discharges, feces and urine of a large proportion (17%) of clinically normal horses. The importance of urine shedding of the virus in transmission of infection is unclear, although the inhalation of aerosols of infected urine might transmit the virus. ERV might be an important but under recognized cause of acute upper respiratory disease in horses. The disease thought to be associated with ERV is characterized by an incubation period of 3–8 days, fever, pharyngitis, pharyngeal lymphadenitis, and a copious nasal discharge which is serous early and becomes mucopurulent later. Viremia is a consistent feature of the early stages of the disease. A cough persists for 2–3 weeks. The uncomplicated disease is mild and self-limiting. Among a group of susceptible horses, there is rapid spread of infection and disease. Studies in England have not identified the virus as an important cause of inflammatory airway disease in racing horses. Virus neutralizing antibody develops within 7–14 days of infection and persists for long periods. Immunity after natural infection is said to be solid and long-lasting. Diagnosis is based on serological testing and tissue culture of the virus, which is environmentally resistant. There is no commercial vaccine available. Planned exposure of young horses to infection has been recommended, but should be reconsidered in light of current knowledge of the prolonged shedding of the virus in urine and feces. The virus appears to have minimal zoonotic potential.10,11

Equine rhinitis virus B has been characterized and approximately 24% of horses in Australia and 86% of horses in Austria have serum neutralizing antibodies to the virus. The role of ERBV in causing disease in horses is unknown.

Parainfluenza-3 virus Upper respiratory tract disease associated with equine parainfluenza-3 (PI-3) is characterized by a mild self-limiting disease which is not clinically distinguishable from the others in the group. The epidemicology and economic importance of disease associated with this agent is unknown.

Equine adenovirus infection Two antigenic types of equine adenovirus, EAdV-1 and EAdV-2, are recognized that cause respiratory disease in foals and adult horses and diarrhea in foals, respectively. Infection with EAdV is worldwide, based on seroepidemiological studies using virus neutralization and complement fixation tests, and affects up to 70% of horses. Horses less than 1 year of age are most likely to have serological evidence of exposure, and are therefore presumably at risk of infection and disease. EAdV usually causes a mild respiratory disease with fever, coughing, nasal discharge and conjunctivitis, although its association with fatal pneumonia in thoroughbred foals is reported. Foals usually acquire the infection from their dams, which secrete the environmentally stable virus in nasal discharge, urine and feces. In Arab foals with inherited combined immunodeficiency adenovirus infection is usually fatal. The virus is not associated with inflammatory airway disease in race horses in England, but has been associated with small outbreak of upper respiratory tract disease. Diagnosis can be made on cell smears taken from conjunctiva or nasal mucosa that reveal characteristic adenoviral intranuclear inclusion bodies. Serological methods include serum neutralization, hemagglutination inhibition, complement fixation, or precipitating antibody tests. The serum neutralization test is most accurate, but the hemagglutination inhibition test is most suitable for a screening test No specific control measures are indicated for normal foals.

Reovirus A reovirus, or a series of serotypes, cause mild upper respiratory tract disease of horses. Infection with these agents appears to be of little clinical or economic importance.

Equine coital exanthema Equine coital exanthema is a venereal disease manifested by papular, then pustular, and finally ulcerative lesions of the vaginal mu cosa, which is generally reddened. The ulcers may be as large as 2 cm in diameter and 0.5 cm deep and are surrounded by a zone of hyperemia. In severe cases the lesions extend onto the vulva and the perineal skin to surround the anus. In the male, similar lesions are found on the penis and prepuce. Many mild cases are unobserved because there is no systemic disease and affected horses eat well and behave normally. The effect on fertility is equivocal although there may be a loss of libido during the active stage of the disease in stallions. Transmission is usually venereal from affected or clinically normal carrier animals in which the infection is thought to be latent in sciatic ganglion. The incubation period is 2–10 days and the course up to complete healing of ulcers is about 14 days. Diagnosis can be achieved by use of virus isolation or demonstration of viral DNA in skin lesions. Secondary bacterial infection may lead to suppurative discharge and a longer course. In some outbreaks lesions occur on the skin of the
lips, around the nostrils, and on the conjunctiva. They may also be present on the muzzle of the foal. Ulcerative lesions of the pharyngeal mucosa also occur in infections with EHV-2 and with EAdV. Ulcerative lesions of the oral mucosa are of great importance because of the necessity to diagnose vesicular stomatitis early. Control can be achieved by use of artificial insemination.10

EQUINE HERPESVIRUSES

Five herpesviruses have been associated with various diseases of horses and foals (equine herpesvirus 1-5, EHV-1 to 5). EHV-1, EHV-3 and EHV-4 are alphaherpesviruses, whereas EHV-2 and EHV-5 are slow-growing gammaherpesviruses. Common names are ‘equine abortion virus’ for EHV-1, ‘cytomegalovirus’ for EHV-2, ‘equine coital exanthema virus’ for EHV-3, and ‘rhinopneumonitis virus’ for EHV-4 (although this term is sometimes used, confusingly, for EHV-1). EHV-1 and EHV-4 show extensive antigenic cross-reactivity and were previously considered subtypes of the same virus (EHV-1), but restriction endonuclease fingerprinting has demonstrated them to be different viruses. EHV-1 is closely related to asine (donkey) herpesvirus 3, which is suggested to be its progenitor.1 Related herpesviruses (asine herpesvirus 1-5) infect and some cause disease in donkeys.1-3 The recently identified asine herpesviruses ASV-4 and ASV-5 cause a fatal interstitial pneumonia in donkeys.3

The disease syndromes attributed to equine herpesvirus infection, which are discussed in the following pages, and the viruses associated with them are:

- **Upper respiratory tract disease** of adult horses, weanlings and older foals is caused principally by EHV-4, although disease attributable to EHV-1 occurs. EHV-2 causes respiratory disease, including pneumonia, of foals, and rarely upper respiratory disease of adults.
- **Abortion** is almost always associated with EHV-1, although rare sporadic cases are associated with EHV-4.
- **Perinatal disease** of foals, including birth of sick and weak foals and development of viral septicemia within 48 hours of birth, is associated with EHV-1.
- **Myelencephalopathy** is associated with EHV-1 and rarely EHV-4.
- **Genital disease** is an unusual manifestation of EHV-1 infection.
- **Coital exanthema** is associated with EHV-3.

Disease associated with EHV-5 has not been identified, although it is suspected to have a role in interstitial pneumonia of adult horses. The diseases associated with EHV-1-4 are discussed below.

ETIOLOGY

Upper respiratory disease of foals and adults is associated with equine herpesvirus 4 (EHV-4), an alphaherpesvirus. The DNA sequence of EHV-4 has been determined.1 There appear to be strains of EHV-4 that vary in virulence, based on severity of clinical disease, but at present it is not possible to differentiate between strains of low and high virulence by laboratory methods.

EPIDEMIOLOGY

Occurrence

Infection with EHV-4 is endemic in horse populations worldwide. The serologic surveys of prevalence of serologic evidence of infection are of limited value as earlier studies used techniques that were unable to differentiate between antibodies to EHV-1 and EHV-4. The few recent serologic surveys using ELISA tests capable of differentiating between antibodies to EHV-1 and EHV-4 demonstrate that almost all horses and foals >60 days of age have evidence of infection by EHV-4.3-6 Young foals can be seropositive as a result of transfer of immunoglobulins from seropositive dams, making determination of the time of first infection, and active seroconversion, difficult. Furthermore, serologic tests are also unable to differentiate between responses to natural infection and to vaccination.

EHV-4 can be isolated from both clinically normal foals and those with signs of upper respiratory disease with similar frequency.7 Shedding of virus is more likely in foals with nasal discharge.7 There is a marked seasonal distribution to the pattern of shedding, with the most frequent detection of shedding being in early autumn (March).7

Upper respiratory tract disease attributable to EHV-4 is very common and probably affects almost all horses during the first 2 years of life.8 EHV-4 rarely causes abortion in mares, septicemia in newborn foals, or myelencephalopathy in adult horses.9

Method of transmission

EHV-4 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges. Foals infected with EHV-4 have prolonged and profuse shedding of virus in nasal secretions. Mediate infection may occur, the virus surviving for 14-45 days outside the animal.

Infections always arise from other horses, both by direct contact and via fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, presumably during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is certainly longer than 14 days. The latency of virus in nasal secretions is 5 months or longer.11
assumed to be lifelong. EHV-4 establishes latency in the trigeminal ganglion, which is the origin of the maxillary branch of the trigeminal (5th cranial) nerve that provides sensory innervation to the nasal mucosa. It is assumed that reactivation of the virus and subsequent virus shedding poses a risk to in-contact, susceptible animals, but this has not been definitively demonstrated in field situations. If this were the case, then clinically normal animals harbor latent virus that during periods of reactivation can infect susceptible animals. If true this feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.

**Risk factors**

**Immunity**

Immunity resulting from natural infection of the respiratory tract is of short duration despite the persistence of serum virus-neutralizing (VN) antibodies. If similar to EHV-1, immunity to EHV-4 is likely associated with cytotoxic T-cell responses because of the importance of cell-associated virus in dissemination of infection throughout the horse. Because of the short duration of immunity an animal can become clinically affected a number of times during its life, although subsequent disease tends to be milder. Foals born to mares with serum antibodies to the virus acquire a protective passive immunity that persists for up to 180 days, provided that they ingest sufficient high quality colostrum. Unfortunately, VN antibodies are not necessarily an indication of resistance to infection.

**Age**

Foals are infected by EHV-4, presumably from the dam or other mares in the band of mares and foals, early in life and excrete large quantities of virus in nasal secretions. Horses are infected repeatedly throughout life, with episodes of disease being less frequent and milder with increasing age. EHV-4 is isolated more frequently from younger than from older horses, suggesting an age-associated decrease in susceptibility to disease.

**Economic importance**

Disease associated with EHV-4 is apparently of considerable economic importance because of the loss of training time and opportunities to perform during convalescence and quarantine. Although the upper respiratory disease is a mild inflammation of the respiratory tract of horses, characterized by coughing and nasal discharge, the importance of the disease is the large numbers of animals affected in an outbreak. Fatalities in uncomplicated cases of rhinopneumonitis are rare.

**PATHOGENESIS**

The pathogenesis of EHV-4 infection and disease is assumed to be similar to that of EHV-1, with the exception that the virus does not commonly cause abortion, neonatal septicemia, or myeloencephalopathy. The virus is inhaled and binds to epithelium of the upper respiratory tract, enters epithelial cells and reproduces. The infection then spreads throughout the respiratory tract, including trachea and bronchioltes, and to lymphoid tissues associated with the respiratory tract. There is a viremia, though this may be of short duration. There is cell death and development of intranuclear inclusion bodies in the respiratory tract and associated lymphoid tissues. The EHV-4 virus then becomes latent as evidenced by isolation of virus from lymph nodes associated with the respiratory tract, and detection of viral genome in trigeminal ganglia, although this has not been a consistent finding.

The factors causing viral recrudescence from these latent sites have not been determined. It should be noted that definitive evidence of viral recrudescence of EHV-4 as a cause of outbreaks of disease is lacking, and experimental induction of recrudescence is achieved only by administration of large doses of corticosteroids.

**CLINICAL FINDINGS**

The classical respiratory tract form of the disease (rhinopneumonitis) is virtually indistinguishable on the basis of clinical signs from the other respiratory tract diseases of horses. There is an incubation period of 2–20 days. Fever, conjunctivitis, coughing and mild inflammation of the upper respiratory tract are the cardinal manifestation of the disease, but apparent infection is common. The temperature varies from 39 to 40.5°C (102.5 to 105°F). There is enlargement, but not abscessation, of the submandibular lymph nodes, especially in foals and yearlings. These signs are more likely to occur in young horses or when horses are assembled in sale barns. Edema of the limbs and diarrhea occur rarely. The length of the illness is usually 2–5 days, although the nasal discharge and cough may persist for 1–3 weeks. Secondary bacterial invasion, usually *Streptococcus equi* subsp. *zooepidemicus*, may exacerbate the clinically inapparent viral pneumonia. Young foals can develop primary viral pneumonia.

EHV-4 only rarely causes abortion or neurologic disease.

**CLINICAL PATHOLOGY**

Results of hematological and serum biochemical examinations are neither specific nor diagnostic. In adult horses with rhinopneumonitis there may be a pronounced leukopenia, due largely to depression of neutrophils.

**Serological tests**

Tests of critical importance in diagnosis and control of equine herpesvirus infections. Serum antibody levels to EHV-1/4 may be determined by ELISA, virus neutralization (VN), complement fixation (CF) tests. The CF and VN tests are not able to differentiate between serotype associated with EHV-1 and EHV-4. As an ELISA using recombinant antigens specific for EHV-1 and EHV-4 is able to differentiate infection by each of these types of equine herpesvirus. Many, if not all, adult horses have serum antibodies to EHV-4 as a result of previous infection or vaccination. Thus the demonstration of antibodies is not in itself sufficient to confirm a diagnosis of the disease. Complement-fixing antibody appears on the 10th–12th day after experimental infection but persists for only a few months. Demonstration of a three- to four-fold increase in the serum concentration of specific complement-fixing antibodies in acute and convalescent serum samples provides persuasive evidence of recent infection, albeit by either EHV-1 or EHV-4. Complement-fixing antibodies persist for only a short time (several months) while VN antibodies persist for over a year, and testing for them is therefore a more reliable means of determining that previous infection with the virus has occurred. Until recently, serological differentiation of antibodies to EHV-1 and EHV-4 was not possible. However, highly specific ELISA tests based on the variable region of the C terminus of glycoprotein G, at least one of which is commercially available, have been developed that can differentiate between antibodies to EHV-1 and EHV-4 in horse serum. The ELISA is reported to be more sensitive, easier to perform, more rapid and more reproducible than the virus neutralization test. Importantly, the ELISA test is able to differentiate between infections associated with EHV-1 and EHV-4.

**Identification of the virus**

In nasal swabs, or blood buffy coat by culture or a PCR test provides confirmation of infection. The use of seminested or multiplex PCR provides rapid identification of EHV-4 viral genome in pharyngeal swabs. The test is at least as sensitive as viral isolation in identifying presence of virus. However, the use of rapid and innovative diagnostic techniques based on enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), immunohistochemical staining with peroxidase, or nucleic acid hybridization probes is often restricted to specialized reference laboratories. Therefore the method of choice for diagnosis of
rhinopneumonitis by diagnostic virology laboratories handling many routine samples continues to be the traditional methodology of cell culture isolation followed by sero-identification of the isolated viruses.\textsuperscript{21} The virus can be isolated in tissue culture, chick embryos and hamsters, from either nasal washings or aborted fetuses.

Samples of nasopharyngeal exudate for virus isolation are best obtained from horses during the very early, febrile stages of the respiratory disease, and are collected via the nares by swabbing the nasopharyngeal area with a 5 x 5 cm gauze sponge attached to the end of a 50 cm length of flexible, stainless steel wire encased in latex rubber tubing. A guarded uterine swab devise can also be used. After collection, the swab should be removed from the wire and transported promptly to the virology laboratory in 1 mL of cold (not frozen) fluid transport medium (serum-free MEM [minimal essential medium] with antibiotics). Virus infectivity can be prolonged by the addition of bovine serum albumin or gelatine to 0.1\% (w/v).\textsuperscript{21}

**NECROPSY FINDINGS**

Fatalities are extremely rare in the respiratory forms of EHV-4 infection.

**Samples for confirmation of diagnosis**

- Virus isolation or identification by fluorescent antibody testing or PCR of nasal swabs or blood.

**DIFFERENTIAL DIAGNOSIS**

The upper respiratory diseases of horses are listed in Table 16.4. There is no specific treatment although antibiotics are often administered to horses with respiratory tract disease to prevent or treat secondary bacterial infection. There is, however, no evidence that antibiotic treatment shortens the duration of the disease or prevents complications.

**CONTROL**

Principles of a control program include:

- Enhancing the immunity of individual horses by vaccination
- Minimizing the risk of introducing EHV-4 infection to the farm or stable
- Hygiene to prevent spread of virus on fomites such as clothes and tack
- Rapid isolation of any horse with disease that could be attributable to EHV-4.

**Vaccination**

Vaccines for protection against rhinopneumonitis contain both inactivated EHV-1 and EHV-4 virus,\textsuperscript{24} presumably because both viruses cause respiratory disease in horses. None of the currently available vaccines consistently prevent infection of vaccinated horses or provide complete protection against disease associated with EHV-4 although a combined EHV-1/ EHV-4 inactivated virus vaccine attenuated the clinical signs of disease in experimentally infected foals.\textsuperscript{25,26} The development of modified live virus vaccines administered intranasally holds promise for effective control of both EHV-1 and EHV-4 in foals and adults.\textsuperscript{24}

**Hygiene**

Standard hygienic procedures should be adopted to avoid spread of the disease, with particular attention being given to the isolation of introduced horses.

**ETIOLOGY**

EHV-1 is an alphaherpesvirus, a DNA virus.\textsuperscript{1} EHV-1 and EHV-4 show extensive antigenic cross-reactivity and were previously considered subtypes of the same virus (EHV-1), but restriction endonuclease fingerprinting has demonstrated both the propensity and difference of the two virus species. There are two recognized strains of EHV-1, although this designation does not appear to have any association with virulence. Currently, it is not possible to differentiate EHV-1 strains of varying virulence based on in vitro characteristic.\textsuperscript{2} Virulence is associated with presence of a functional gp2 protein, which is apparently responsible for viral egress from infected cells,\textsuperscript{3} and glycoprotein D and cell surface glycosaminoglycans that are needed for efficient entry of EHV-1 into cells.\textsuperscript{4}

The most important clinical syndromes associated with EHV-1 infection are abortion, neonatal septicaemia, and myeloencephalopathy. Upper respiratory tract disease of adult horses, weanlings and older foals is caused principally by EHV-4, although outbreaks attributable to EHV-1 occur. Genital disease is an unusual manifestation of EHV-1 infection. Infection with EHV-1 causes retinitis and fatal disease in camelds.\textsuperscript{5,6} EHV-1 also causes disease in wild equids including zebras.\textsuperscript{7}
infection. Serologic surveys, which provide an index of the extent of infection in the sampled population, performed before 1995 were hindered by the lack of an assay able to differentiate immune responses to EHV-1 from those to EHV-4. Furthermore, the advent of vaccines eliciting serum antibodies against EHV-1, and the inability of diagnostic tests to differentiate between antibodies induced by vaccination or natural infection, complicates assessment of the prevalence of serum antibodies to EHV-1/4. Seroprevalence of EHV-1 specific antibodies is 9–28% in adult Thoroughbred horses, 26% of Thoroughbred brood mares, 11% of Thoroughbred foals, and 46–68% of 1 and 2-year-old Thoroughbred race horses in Australia. Sixty-one percent of 82 normal horses and horses with upper respiratory tract disease had antibodies to EHV-1 in New Zealand.

Upper respiratory tract disease associated with EHV-1 infection has been suggested to occur as outbreaks, although this is not well documented. Signs of infectious upper respiratory disease affected 20% of Thoroughbred race horses at one race track in Canada over a 3-year period, and seroconversion to EHV-1 occurred in 5–18% of these horses whereas the vast majority of horses seroconverted to influenza. However, all horses that seroconverted to EHV-1 also either seroconverted to influenza virus or had been recently vaccinated with a vaccine containing EHV-1. These results suggest that the stress of influenza disease may have triggered reactivation of latent EHV-1 infection in some horses, suggesting that EHV-1 did not have a primary role in the outbreak of respiratory disease. Similarly, in England, EHV-1 was not associated with clinical respiratory disease in Thoroughbred race horses, EHV-1 was isolated from foals with purulent nasal discharge and respiratory disease concurrent with neurologic disease among the dams in Australia. Abortion due to EHV-1 occurs as both sporadic cases and as epizootics (abortion storms). Approximately 3% of abortions in mares are attributable to EHV-1 infection, although the actual incidence probably varies widely among years and geographical regions. Outbreaks of EHV-1 abortion and birth of nonviable foals occurs sporadically on farms with sometimes catastrophic losses. Loss of foals through abortion or birth of nonviable foals can be as high as 28% of pregnant mares on the farm. Initial cases can, in the absence of appropriate control measures, rapidly spread the infection. Vaccination with killed EHV-1 vaccine during late gestation does not reliably prevent the disease, although conventional wisdom is to ensure that mares are well vaccinated (see 'Control' below). EHV-4 rarely causes abortion in mares. Disease of neonates associated with EHV-1 occurs both sporadically and as outbreaks in which up to 25% of foals may be affected. Foals infected in utero usually die soon after birth, while those infected in the period after birth may have milder disease and a lower mortality rate (6%). One-third of viremic foals may not seroconvert, based on the complement fixation test.

Myeloencephalopathy occurs as sporadic cases but more often presents as an epizootic within a stable or barn or within a localized area. Morbidity rates in exposed horses range from 1 to 90% with mortality rates of 0.5–40%. Pregnant or nursing mares are suggested to be at greater risk of this disease, but outbreaks occur on premises, such as riding schools or race tracks, where there are no foals or pregnant mares.

Method of transmission

EHV-1 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges or aborted fetuses. The virus gains access to the body after binding to respiratory mucosal epithelium. Other routes of infection are not recognized.

The virus is efficiently transmitted to contact animals and rapid spread of infection results from close contact of an infected animal with susceptible horses. Infection can spread over short distances in the absence of physical contact or fomite transmission. This likely occurs by airborne spread of virus in droplets of aerosolized nasal secretions.

Infections always arise from other horses, either by direct contact or via fomites. Mediate infection from virus on fomites such as tack, veterinary equipment, vehicles, and housing occurs because the virus survives for 14–45 days outside the animal. The source of the virus is always on of the following:

- A horse or foal with active infection
- A fetus, fetal membranes, or reproductive tract secretions of a mare immediately after abortion or birth of a weak foal
- Virus shed by horses in which latent infection has reactivated.

Horses and foals are infectious during the active stage of disease and, because horses become latently infected, during subsequent periods of viral reactivation and shedding. There is good circumstantial evidence, such as the occurrence of abortion, neonatal disease, or myeloencephalopathy in closed herds, to support a role for latency and reactivation in the genesis of the disease. The duration of latency is unknown but is assumed to be lifelong. Latent EHV-1 virus is detectable in the trigeminal ganglion and CNS/CD8 lymphocytes. Reactivation of the virus might not result in clinical signs in the host animal but there is shedding of virus in nasal secretions. Consequently, clinically normal animals harbor latent virus that can infect susceptible animals during periods of reactivation. This feature of the disease has obvious importance in the prevention, control, and management of outbreaks of disease.

Abortion storms are usually attributable to an index case that is:

- A latently infected mare that sheds virus from the respiratory tract, but does not abort
- A mare that aborts an infected foetus
- A mare that sheds virus from the respiratory tract, and then aborts

Mares usually, but not always, abort from EHV-1 infection only once in their lifetime. A likely scenario in abortion storms is the reactivation of latent virus in a resident horse with subsequent shedding of virus in nasal secretions or, if the mare aborts, fetal tissues and uterine fluids. Contamination of the environment or horse-to-horse contact spreads infection to susceptible cohorts (primary transmission). The infected cohorts then further spread the virus to other horses in that band of mares (secondary transmission), which then spread infection among other bands of mares and foals, paddocks or fields of horses, or farms (tertiary transmission).

Outbreaks of myeloencephalopathy likely occur through similar mechanisms. Most outbreaks are associated with an index case or introduction of a horse with signs of infectious respiratory disease, with subsequent development of new cases in horses that have either direct or indirect (aerosol or fomite) contact with the index case. It has recently been recognized that horses with clinical signs of myeloencephalopathy can spread the disease, contrary to previous supposition. This has important implications for handling and care of affected horses, especially those severely affected horses that may be referred for intensive or specialized care.

Cycling of infection

Studies on Thoroughbred stud farms in Australia have demonstrated the temporal sequence of events that contribute to spread of EHV-1 infection in that region.
and these studies likely have relevance to other regions of the globe. There is a cyclical pattern in which horses are infected at a young age and the source of infection is, depending on the age of the foal, either its dam or other foals. Foals are infected by EHV-1 and shedding virus in nasal secretions as young as 11 days of age, often without development of clinical signs but usually associated with mucopurulent nasal discharge. Peak incidences of cases of respiratory disease associated with EHV-1 are late during the foaling season before weaning, and again after weaning when foals from several groups are housed together. The source of infection in foals before weaning is mares and, as the number of foals in the herd increases over the course of the foaling season, other foals. Weanlings spread the disease among their herd during the period shortly after weaning when foals from more than one group are mixed. The incidence density of new cases among weanlings can be as high as 13 new cases per 1000 foal weeks. The disease associated with these outbreaks is mild and without long term consequences to the foal or weaning. However, the presence of foals excreting large quantities of EHV-1 has the potential to increase the risk of viral abortion in late term mares in contact with these foals. Furthermore, presence of respiratory disease associated with EHV-1 and shedding of virus by foals is associated with development of myeloencephalopathy in mares.

Risk factors

Immunity

Immunity against respiratory disease and resulting from natural infection of the respiratory tract is of short duration despite the persistence of serum virus-neutralizing (VN) antibodies. The cell-associated nature of the viremia and lack of expression of viral antigens on the surface of infected cells contributes to the poor efficacy of humoral immunity. Immunity to EHV-1 is mediated by cytotoxic T cells, which explains the limited efficacy of inactivated virus vaccines that have minimal effect in stimulating cytotoxic T cells despite being capable of inducing a humoral immune response. The presence of EHV-1 cytotoxic T cell precursors correlates well with protection from experimental infection, and some of the EHV-1 antigens (‘early proteins’) responsible for this resistance have been identified. Because of the short duration of immunity an animal may become clinically affected by respiratory disease a number of times during its life, although subsequent disease tends to be milder. Mares usually only abort from EHV-1 infection once in their lifetime and there are no reports of horses developing myeloencephalopathy more than once.

Lack of antibodies to EHV-1 was identified as a risk factor in an outbreak of EHV-1 myeloencephalopathy in a herd of mares with foals at foot. Mares with strong antibody responses to EHV-1 did not develop disease.

Economic importance

Disease associated with EHV-1 is of considerable economic importance because of the loss of training time and opportunities to perform during convalescence and quarantine, the loss of pregnancies during abortion storms, and deaths due to myeloencephalopathy and infection of neonates.

PATHOGENESIS

The three organ systems involved in clinical disease associated with EHV-1 infection are the respiratory tract, uterus and placenta, and central nervous system. The common final pathway for injury in each of these body systems is damage to vascular endothelium with subsequent necrosis, thrombosis, and ischemia.

Following EHV-1 exposure to the upper respiratory tract, virus can be detected in the soft palate and main stem bronchus within 12 hours, and at all levels of the respiratory tract by 24 hours. In the respiratory tract there is an initial phase after infection in which there is rapid proliferation of the virus in the nasal, pharyngeal and tonsillar mucosae, with subsequent penetration and infection of local blood vessels. This is followed by a systemic, viremic phase in which the virus is closely associated with blood lymphocytes, from which it can be isolated. Infection induces increased production of interferon gamma by T-lymphocytes. Absence of viral antigens on the surface of EHV-1 infected peripheral blood mononuclear cells explains their ability to avoid complement-mediated lysis. This activity, combined with the immunosuppression that accompanies EHV-1 infection, allows dissemination of the infection to the reproductive tract and central nervous system. Immunosuppression is mediated by production in EHV-1 infected cells of an ‘early protein’ that interferes with peptide translocation by the transporter associated with antigen processing. Immunosuppression is evident as reduced in vitro proliferation of peripheral blood mononuclear cells and down regulation of expression of major histocompatibility complex class I molecules on the surface of infected cells. It is from this point that the invasion of lungs, placenta, fetus and nervous tissue occur. Movement of infected mononuclear cells into target tissues is associated with expression of adhesion molecules by endothelium in the gravid uterus and in leukocytes. Viral infection of endothelium results in death of endothelial cells, inflammation, activation of clotting factors and formation of blood clots in small vessels. This thrombotic disease causes ischemia of neighboring tissues with subsequent necrosis and loss of function. Another theory is that deposition of antigen–antibody complexes in small vessels results in an Arthus reaction with subsequent ischemia, necrosis and loss of function. However, recent demonstration that mares with no antibody titer to EHV-1 were at increased risk of developing myeloencephalopathy does not support a role for type III hypersensitivity in this disease. Regardless of the underlying mechanism, clinical signs are a result of vasculitis and necrosis of tissue in the central nervous system and reproductive tract. This is in contrast to neurologic disease associated with herpesvirus in other species, in which the nervous system disease is a direct result of infection of neural tissues.

Abortion is caused by damage to the placenta, endometrium or fetus. Placental lesions include vasculitis, focal thrombosis and infarction of the microcotyledons of the pregnant uterus. The fetus is infected and there are diagnostic lesions present in many aborted foals, including massive destruction of lymphocytes in the spleen and the thymus. In those abortions in which there is no lesion or evidence of virus infection in the foal, there may be extensive damage to the endometrium due to an endothelial lesion and its attendant vasculitis, thrombosis and secondary ischemia.

Foals that are infected in utero but survive to full term may be stillborn or weak and die soon after birth with pulmonary, hepatic, and cardiac lesions. EHV-1 infection in foals not infected before or at birth is usually a self-limiting, mild infection of the upper respiratory tract with accompanying leukopenia and a transitory immune suppression, although uveitis and occasionally death occur in a small number of foals. Virus can be isolated from the nasal mucus and the blood of the foal for some time after clinical signs have disappeared.

The pathogenesis of myeloencephalopathy in horses contrasts with herpesvirus encephalitis of other species in which there is viral infection of neuronal tissue. Viral infection of endothelium results in death of endothelial cells, inflammation, activation of clotting factors and formation of blood clots in small vessels. This thrombotic disease causes ischemia of neighboring tissues with subsequent necrosis and loss of function. Another theory is that deposition of antigen–antibody complexes in small vessels results in an Arthus reaction with subsequent ischemia, necrosis and loss of function. However, recent demonstration that mares with no antibody titer to EHV-1 were at increased risk of developing myeloencephalopathy does not support a role for type III hypersensitivity in this disease. Regardless of the underlying mechanism, clinical signs are a result of vasculitis and necrosis of tissue in the central nervous system and reproductive tract. This is in contrast to neurologic disease associated with herpesvirus in other species, in which the nervous system disease is a direct result of infection of neural tissues.
CLINICAL FINDINGS

EHV-1 infection manifests as several forms of disease on a farm such that nervous system involvement can occur in an outbreak in which abortion and respiratory disease also feature although more commonly one form of the disease (myeloencephalopathy or abortion) occur alone or with mild respiratory disease. Foals, stallions and mares can be affected with one or other form of the disease, although the disease is most commonly seen in adult horses. Onset of neurologic signs is usually, but not invariably, preceded by cases of respiratory disease, fever, limb edema, or abortion.

Respiratory disease

The classical respiratory tract form of the disease (rhinopneumonitis) is virtually indistinguishable on the basis of clinical signs from the other upper respiratory tract diseases of horses and is identical to that associated with EHV-4.

Abortion

Outbreaks of abortion might not be preceded by clinically apparent respiratory disease. The incidence of abortion is highest in the last third of pregnancy, particularly in the 8 to 10-month period but can occur as early as the 5th month. Abortion occurs without premonitory signs and the placenta is usually not retained. There is frequently no mammary development. Affected mares sometimes prolapse the uterus. Some foals are stillborn whereas others are weak and die soon after birth.

Abortion storms are often long lasting, with a period of 17–22 days separating the index case from cases caused by secondary transmission of the virus, suggesting an incubation period of 2–3 weeks. Experimental infections induce abortion 15 to 65 days after intranasal inoculation of the virus. While most abortions then occur within one month of the first secondary cases, abortions on a farm can continue for many months.

Neonatal viremia and septicemia

In-utero EHV-1 infection causes abortion or the birth of infected foals, some of which are normal at birth, but become weak and die within 3–7 days of birth with signs of respiratory distress and septicemia. A less severe form of the disease, characterized by pyrexia, nasal discharge and chorioretinitis, occurs in slightly older foals that are apparently infected after birth. Affected foals that survive sometimes do not have serum antibodies to EHV-1. Death may be associated with secondary bacterial infection with Escherichia coli or Actinobacillus equuli, although EHV-1 infection alone is sufficient to cause death.

Myeloencephalopathy

The disease initially occurs in an index case, which might or might not have had signs of infectious respiratory disease alone or with signs of neurologic disease. Signs of neurologic disease develop in other horses approximately 2 weeks after disease in the index case. Disease then develops in a number of horses over a short period of time (3–10 days).

Fever, without signs of respiratory disease, often precedes signs of neurologic disease by 24–72 hours. The onset of neurologic signs is usually rapid, with the signs stabilizing within 1–2 days. Signs are variable but usually referable to spinal white matter involvement. Affected horses have variable degrees of ataxia and paresis manifest as stumbling, toe dragging, pivoting and circumduction that is most severe in the hind limbs. Signs are usually symmetrical. There is often hypotonia of the tail and anus.

Fecal and urinary incontinence are common and affected horses often dribble urine, have urine scaling of the skin of the perineum and legs, and require manual evacuation of the rectum. The severity of signs can progress to hemiplegia or paraplegia manifesting as recumbency and inability to rise. Less commonly, cranial nerve deficits, such as lingual or pharyngeal paresis, head tilt, nystagmus or strabismus, are present. Affected horses are usually alert and maintain their appetite.

Severity of neurologic disease varies among horses within an outbreak, and the prognosis is related to the severity of disease. In general, horses that become recumbent have a poor prognosis for both short- and long-term survival despite intensive nursing care. However, less severely affected horses have a good prognosis for survival, with case fatality rates are low as 2–3% in some outbreaks. Horses with mild signs of neurologic disease often recover completely and return to their previous level of performance, although some have persistent neurologic deficits after one year.

CLINICAL PATHOLOGY

Results of hematological and serum biochemical examinations are neither specific nor diagnostic. EHV-1 infection of adult horses results in leucopenia that is attributable to both neutropenia and T-cell lymphopenia, with B-cell lymphocytosis occurring during the recovery period. EHV-1 septicemia of foals is characterized by profound leukopenia, neutropenia with a left shift and lymphopenia.

Cerebrospinal fluid (CSF) of horses with EHV-1 encephalomyelopathy is characteristically xanthochromic and has an increased total protein concentration (>1 g/L) with a normal white cell count. The interpretation of EHV-1 antibody in CSF is uncertain, although normal horses are not expected to have detectable antibodies to EHV-1 in the CSF.

Serological tests are of critical importance in diagnosis and control of equine herpesvirus infections. Many horses have serum antibodies to EHV-1 and EHV-4 as a result of previous infection or vaccination. Thus the demonstration of antibodies is not in itself sufficient to confirm a diagnosis of the disease. Complement-fixing antibody appears on the 10th–12th day after experimental infection but persists for only a limited period. Demonstration of a three- to four-fold increase in the serum concentration of specific complement-fixing antibodies in acute and convalescent serum samples provides persuasive evidence of recent infection. Complement-fixing antibodies persist for only a short time (several months) while VN antibodies persist for over a year, and testing for them is therefore a more reliable means of determining that previous infection with the virus has occurred. Until recently, serological differentiation of antibodies to EHV-1 and EHV-4 was not possible. However, highly specific ELISA tests based on differences between EHV-1 and EHV-2 in the variable region of the C terminus of glycoprotein G, at least one of which is commercially available, have been developed that can differentiate between antibodies to EHV-1 and EHV-4 in horse serum. The ELISA is reported to be more sensitive, easier to perform, more rapid and more reproducible than the virus neutralization test. Importantly, the ELISA test is able to differentiate between infections associated with EHV-1 and EHV-4.

Identification of the virus in nasal swabs, or blood buffy coat by culture or a PCR test provides confirmation of infection. The use of seminested or multiplex PCR provides rapid identification of EHV-1 viral genome in pharyngeal swabs. The test is at least as sensitive as viral isolation in identifying presence of virus. However, the use of rapid and innovative diagnostic techniques based on enzyme-linked immunosorbent assay (ELISA), polymerase chain reaction (PCR), immunohistochemical staining with peroxidase, or nucleic acid hybridization probes is often restricted to specialized reference laboratories. Therefore the method of choice for diagnosis of EHV-1-associated disease by diagnostic virology laboratories handling many routine samples continues to be the traditional methodology of cell culture isolation followed by sero-identification of the isolated
The laboratory examination of aborted fetuses should include a search for virus by tissue culture and immunohistochemical or PCR techniques, as well as a histological examination of the lung and liver for the presence of inclusion bodies. A direct fluorescent antibody test has also been used. A serological examination of the foal may provide useful information in those cases where attempts at isolation are negative but seroconversion has occurred. However, a recent study found that fetal serology was an unreliable means of diagnosing EHV-1 abortion and that IHC was slightly more sensitive than virus isolation.

Samples for confirmation of diagnosis
- Virology – chilled lung, liver, spleen, thymus and thoracic fluid of aborted fetuses or neonates. Spinal cord or brain of horses with nervous disease (VI, PCR, FAT, serology)
- Histology – fixed lung, liver, spleen, thymus, trachea from fetuses or neonates
- Fixed brain and spinal cord from several sites, as well as Bourin’s-fixed eye should be examined in adults with nervous disease (I.M, IHC).

**DIFFERENTIAL DIAGNOSIS**

Respiratory disease may be associated with a variety of agents (Table 16.4).
- Abortion can be associated with leptospirosis, *Salmonella abortus equi*, placentitis associated with Streptococcus zooepidemicus or *Escherichia coli*, associated with mare reproductive loss syndrome, or congenital abnormalities, among other causes. When other pregnant mares are at risk in abortion in a late-term mare should always be considered to be due to EHV-1 until proved otherwise.
- Neurologic diseases with clinical presentations similar to that associated with EHV-1 include rabies, equine protozoal myeloencephalitis, neunitis of the cauda equina (equine polyneuritis), trauma, acute spinal cord compression (cervical stenotic myelopathy) and equine degenerative myelopathy. Fever is rare in other neurologic diseases of horses and any horse with neurologic disease and fever or a history of fever within the previous week should be considered to have EHV-1 myeloencephalopathy. Outbreaks of posterior paraparesis or ataxia, especially in horses without fever, should prompt consideration of ingestion of intoxicants such as *Astragalus spp.*, *Swainsonia spp.*, os-sorhghum. Rye grass staggers can produce similar signs of ataxia. Neoronal septicemia may be associated with *E. coli*, *Streptococcus* spp. and other bacteria, especially in foals with failure of transfer of maternal immunoglobulins.

**TREATMENT**

Because of the highly contagious nature of EHV-1 infections, horses with respiratory disease, abortion or neurologic disease, especially if these occur as an outbreak, should be isolated until the cause of the disease is identified.

There is no specific treatment for the diseases associated with equine herpesvirus infection although acyclovir was used to treat horses in recent outbreaks of myeloencephalopathy. The drug is effective against EHV-1 in vitro and pharmacokinetic studies suggest that administration of 10 mg/kg orally every 4–6 hours (five times daily) or 10 mg/kg IV every 8 hours results in acceptable concentrations of drug in the blood. However, other studies have not demonstrated adequate concentrations of the drug in blood after oral administration of 20 mg/kg. The efficacy of this drug in treatment of EHV-1 myeloencephalopathy has not been determined.

Antibiotics are often administered to horses with respiratory tract disease to prevent or treat any secondary bacterial infection. There is, however, no evidence that antibiotic treatment shortens the duration of the disease or prevents complications.

Horses with EHV-1 myeloencephalopathy require intense supportive care. Administration of corticosteroids to these horses is controversial, but many clinicians administer dexamethasone sodium phosphate (0.05–0.25 mg/kg IM every 12–24 h) or prednisolone (1–2 mg/kg orally or parenterally every 24 h) for 3–5 days. Administration of corticosteroids may be contraindicated because of the presence of replicating virus in affected horses. Nursing care to prevent urine scalding, pressure sores and pneumonia is important in horses with myeloencephalopathy. Recumbent or severely ataxic horses should be supported to stand if at all possible. While a rope tied to the tail and swung over an overhead beam may be used to assist the horse to stand, a sling may be necessary to support more severely affected horses.

**Neonatal foals** with septicaemia should be treated aggressively with antibiotics and supportive care, including enteral or parenteral nutrition and fluid administration (see ‘Principles of providing care to the critically ill neonate’). Treatment with acyclovir has been reported. Failure
of transfer of passive immunity should be rectified with oral or intravenous administration of colostrum or plasma, respectively.

CONTROL

Recommendations for programs to prevent introduction of infection and to control disease outbreaks are available from several sources.\textsuperscript{12,66}

Prevention of infection

The principles are:\textsuperscript{12}

- enhanced immunity, currently attempted by vaccination
- subdivision and maintenance of the farm population in groups of horses to minimize spread of the infection
- minimize risk of introduction of infection by new horses
- minimize risk of reactivation of latent infection in resident horses
- develop plans for implementation of these routine control measures, and for actions in the event of an abortion
- educate management and staff as to the importance of strict adherence to these procedures.

The relative importance of each of the above measures has not been determined, but implementation of control measures, including allocation of mares to small bands based on anticipated foaling date, quarantine of new introductions, and vaccination of pregnant mares has reduced the incidence of EHV-1 abortion in central Kentucky. The most striking association has been an apparent reduction in the incidence of abortion storms. It must be emphasized that vaccination does not replace any of the other management procedures in control of this disease and that abortions have occurred among vaccinated mares on farms on which the other management procedures have been ignored.

Vaccination

Vaccination against respiratory disease and abortion associated with EHV-1 is widely practised despite lack of clear cut evidence that vaccination reduces the incidence or severity of either of these diseases. Information regarding field efficacy of equine herpesvirus vaccines is lacking, and that derived from experimental challenge models is often contradictory or incomplete.\textsuperscript{67} Give these caveats, the following recommendations are made based on generally accepted practices.

None of the currently available vaccines consistently prevent infection of vaccinated horses or provide complete protection against disease associated with EHV-1. The principal objective of vaccination has been to protect mares against abortion associated with EHV-1, although vaccines intended to prevent rhinopneumonitis and containing both EHV-1 and EHV-4 are available. Additionally, vaccination of mares is intended to reduce transmission of EHV-1 to foals in an attempt to interrupt the cyclical nature of infection on stud farms.\textsuperscript{6,8} Vaccines consisting of a modified live EHV-1, inactivated EHV-1, or a mixture of inactivated EHV-1 and EHV-4 are available for intramuscular or intranasal administration to horses.\textsuperscript{69} Both inactivated and modified live EHV-1 vaccines elicit virus-neutralization and complement fixation antibody responses in horses,\textsuperscript{1} although high antibody titers are not necessarily related to resistance to infection.\textsuperscript{69}

Resistance to infection might be more closely related to cytotoxic T-cell responses.\textsuperscript{33} Widespread use of a combined EHV-1 and EHV-4 killed virus vaccine in Australia has not reduced serologic evidence of infection in foals on farms where mares are vaccinated,\textsuperscript{68} although the vaccine was effective in preventing disease induced by experimental infection. Complicating assessment of vaccine efficacy is the variable response to vaccination by some mares and foals, with certain animals having minimal responses to vaccination which in other horses elicits a strong immune response.\textsuperscript{30} Efforts are underway to develop modified live vaccines that can be administered intranasally.\textsuperscript{67} Intranasal administration of one such EHV-1 vaccine induced protection against experimentally induced EHV-1 (and EHV-4) respiratory disease and abortion in mares, and prevented infection of foals even when administered in the presence of maternally-derived antibodies.\textsuperscript{76-77} An alternative approach is the development of subunit vaccines using the envelope glycoprotein D which has been shown to elicit protective immunity in laboratory animal models of EHV-1 disease and administration of which induces virus neutralizing antibody and glycoprotein D-specific ELISA antibodies in horses.\textsuperscript{74} However, at the time of writing these products are not commercially available nor has their efficacy in field situations been demonstrated.

Despite the incomplete protection afforded by vaccines, vaccination against EHV-1 is an important part of most equine herd health programs in the vaccination of pregnant and non-pregnant mares, foals, and adult horses. The intent of vaccination of mares is to prevent abortion associated with EHV-1. One inactivated virus vaccine is reported to decrease the incidence of abortion by 65%, although others have not been able to replicate this success and there are reports of abortion storms on farms of well vaccinated mares.\textsuperscript{1,18,75} An inactivated virus vaccine containing EHV-1 and EHV-4 prevented abortion in five of six mares exposed experimentally to EHV-1, whereas all six non-vaccinated mares aborted.\textsuperscript{46} Mares are vaccinated with the inactivated vaccine during the 5th, 7th, and 9th months of gestation. Additional vaccinations at breeding and 1 month before foaling are recommended by some authorities.

Foals are an important source of infection (see 'Infection cycling' above) and control of infection in foals is considered critical to control of infection on a farm.\textsuperscript{1} Consequently, attention has been paid to the responses of foals to vaccination at various ages, given the risk of passive immunity interfering with vaccination and the early age at which foals are infected by EHV-1.\textsuperscript{9} Current recommendations vary with some authorities recommending vaccination of foals after 5 months of age, to avoid the interfering effect of passive immunity on response to vaccination.\textsuperscript{76} However, vaccination of foals at this age likely misses the period of time when foals are first infected by EHV-1 from their dam or other mares in the band.\textsuperscript{9} One recommendation is that foals be vaccinated in their 3rd month, with revaccination 1 month and 6 months later. Modified live virus vaccine is given to foals at 3–4 months of age, non-pregnant mares and other horses as two doses administered 3 months apart, followed by revaccination every 9 months. Because of the short duration of immunity following vaccination, frequent vaccination, perhaps at intervals as short as 3 months, of horses at high risk is recommended. However, the efficacy of such a program is uncertain.

The efficacy of vaccination in preventing myeloencephalopathy appears to be minimal and there is concern that well vaccinated horses might be at increased risk of the disease, although this has not been conclusively demonstrated and there is evidence to the contrary.\textsuperscript{16}

Subdivision of horses on a farm

Maintenance of small groups of horses of similar age and reproductive status is recommended to minimize the chances of spread of infection.\textsuperscript{32} Pregnant mares, after weaning of foals, should be maintained in a herd that does not have access to foals, weanlings, nonpregnant mares or other equids (donkeys). Similarly, weaned foals should be separated from horses of other ages in recognition of the high rate of infection and viral shedding in weanlings.\textsuperscript{7} Failure to adhere to these procedures can result in rapid spread of infection and abortions among at risk
Pregnant mares should be combined into small groups (~10) early in pregnancy based on their anticipated foaling dates.\textsuperscript{12,66} Multiparturion mares should not be mixed with mares that are pregnant for the first time.

Management practices should be introduced to minimize the opportunities for viral spread. Ideally, pregnant mares are handled using facilities separate to those used to handle mares with foals or weanlings. If common facilities must be used, pregnant mares should be handled first, after thorough cleaning of the facility, followed by mares with foals and finally weanlings and other horses.

Minimize risk of introduction of infection

The only sources of virus are recrudescence of latent infection and introduction by newly arrived horses shedding virus. All horses must be considered as potentially shedding EHV-1 on arrival at a farm and should be isolated from resident horses. Introduction of new horses to the small groups of pregnant mares should be avoided if at all possible, or if absolutely necessary preceded by a 21 day isolation period.\textsuperscript{23,66} If at all possible, avoid mingling resident and non-resident mares even after quarantine of non-resident animals.

Prevention of reactivation of latent infection

The factors inciting reactivation of latent infection and viral shedding are unknown. However, stressful events, such as transportation or other disease, have the potential to cause reactivation of latent infection. For this reason pregnant mares should not be shipped within 8 weeks of expected foaling and all efforts, including vaccination, should be made to prevent other infectious diseases.\textsuperscript{66}

Control of outbreaks

The principles underlyng control of abortions due to EHV-1 include:\textsuperscript{12,66}

- Early and rapid diagnosis
- Prevention of spread of infection
- Treatment of individual cases

Rapid diagnosis

Every abortion in a late term mare should be considered to be associated with EHV-1 until proven otherwise. Therefore, rapid and early diagnosis of the abortion in important in instituting control measures. Means of diagnosing EHV-1 abortion are detailed above. In regions with large numbers of breeding mares, all abortions in mares should be investigated by detailed post mortem examination of the fetus and serologic examination of the mare.

Prevention of spread

Diligent and concerted efforts must be made to prevent dissemination of infection from the initial focus. Infected fetal tissues and fluids, and contaminated materials such as bedding, should be placed in impervious containers and either transported to a laboratory for examination or destroyed by incineration. Samples for laboratory examination should be handled in a manner to prevent spread of infection. Facilities and equipment that might have been contaminated should be disinfected by thorough cleaning followed by application of a phenolic or iodophor disinfectant.\textsuperscript{23}

The mare should be isolated until results of laboratory examination are negative for EHV-1 or until the second estrus, at which time it is unlikely that there is shedding of virus from the reproductive tract.\textsuperscript{66} Other mares in the same band as the mare that aborted should be considered exposed and at risk of abortion. These mares should be held in strict isolation until the results of laboratory examination are negative for EHV-1, or until they foal or abort. Other recommendations for horse movement include:

- When an abortion occurs on the stud, no mares should be allowed to enter or leave it until the possibility of EHV-1 infection is excluded. However, maiden and barren mares, i.e. mares that have foaled normally at home but that are not in foal, coming from home studs where no signs of the disease are occurring, may be admitted because they are considered to be not infected.
- If EHV-1 infection is identified on the stud, all pregnant mares due to foal that season (i.e. late pregnant mares) should remain at the stud until they have foaled. The incubation period for EHV-1 abortion ranges between 9 and 121 days.
- All non-pregnant animals and mares that have foaled should remain at the stud for 30 days after the last abortion.

The main problem that arises in this program is in deciding what to do with mares that come into contact with the respiratory disease but not the abortion disease. This may occur very early in pregnancy and prolonged isolation would be onerous. The decision usually depends on the owner's risk aversion and the availability of facilities to maintain long-term isolation.

Control of outbreaks of myeloencephalopathy

Outbreaks of EHV-1 induced neurologic disease often occur in riding schools and similar situations where there is constant movement of horses on and off the property. As such it is exceedingly difficult to institute control measures that prevent introduction of the disease and that are compatible with the use of the horses. Having said that, the principles outlined above for preventing introduction of infection on to breeding farms also apply for prevention of myeloencephalopathy at riding stables.

Outbreaks of neurological disease attributable to EHV-1 should be handled as follows:\textsuperscript{12}

- Affected horses should be isolated as there is strong evidence that these horses are infectious\textsuperscript{22}
- The diagnosis should be confirmed by virus isolation, PCR, or histological examination of tissues from affected horses that die or are euthanized.
- There should be no movement of horses on or off the premises for at least 21 days after the last case has occurred\textsuperscript{62}
- Movement among bands of horses on the farm should be avoided.
- Bands of horses should be monitored for clinical, serological or virological evidence of infection.
- Animals should leave or move between bands only when there is no evidence of continued active infection in their group.
- Vaccination in the face of an outbreak of EHV-1 myeloencephalopathy is not recommended.
- Prophylactic use of acyclovir has been reported although the efficacy of this practice is unknown.\textsuperscript{64}

EQUIINE HERPESVIRUS 2 (CYTOMEGALOVIRUS)

ETIOLOGY
EHV-2 is a slow-growing gamma-herpesviruses.1 The viral genome has been elucidated.2 There is considerable antigenic, genetic and biologic heterogeneity among EHV-2 isolates which might reflect variations in pathogenicity.3

EPIDEMIOLOGY
Almost all adult horses and foals over 2 months of age have serologic evidence of infection by EHV-2.3-6 EHV-2 was cultured from bronchial or other lymph nodes in 97% of horses sampled at an abattoir and from blood of 31–76% of live adult horses (clinically normal or with respiratory disease) in Europe and New Zealand.3,7,8 Virus was isolated from blood of 76 of 77 normal foals examined in the United States8 and in all of 16 foals from a stud with endemic respiratory disease in New Zealand.9 Viral genome was detected in blood of ~70% of live, adult horses in Europe and in trigeminal ganglion 6 of 12 seropositive ponies.8,9 Thirty-four virus isolates were obtained from peripheral blood leukocytes of 139 horses in Poland.10 Viral DNA was detected in blood samples of all foals examined in Europe,11 These data demonstrate the ubiquitous nature but uncertain clinical significance of EHV-2 infection of horses worldwide.

The frequency with which disease attributable to EHV-2 occurs in horses is uncertain. In one report, 10 of 16 foals naturally infected with EHV-2 developed respiratory disease, and two died.5 EHV-2 is isolated from tracheal aspirates of foals with respiratory disease much more often than it is isolated from tracheal aspirates of foals without respiratory disease.5 Isolation of EHV-2 is statistically associated with upper respiratory disease in horses,3 and experimental infection causes conjunctivitis, lymphadenopathy, and coughing.12 The virus is isolated more frequently from eyes of horses with keratoconjunctivitis than from eyes of normal horses, suggesting a role for EHV-2 in this disease.13 The observation that EHV-2 can be isolated more frequently from the blood of horses with upper respiratory disease, ataxia or abortion might indicate a causative role for the virus, or that intercurrent disease induces reactivation of EHV-2 infection.5

EHV-2 is highly infectious, and transmission probably occurs by the inhalation of infected droplets or by the ingestion of material contaminated by nasal discharges. Virus is secreted in nasal and ocular discharges of recently infected horses, and in nasal secretions and tracheal fluid of foals with respiratory disease associated with natural infection.5,5,7 If survival ex vivo is similar to that of the other equine herpesviruses, mediate infection may occur for 14–45 days, although this has not been specifically investigated for EHV-2.

Infections always arise from other horses, both by direct contact and by fomites. Horses and foals are infectious during the active stage of disease and, because horses become latently infected, during subsequent periods of viral reactivation and shedding. The duration of latency is unknown but is assumed to be lifelong.4 Latent EHV-2 virus is detectable in the trigeminal ganglia, lymph nodes, and peripheral blood monocytes of clinically normal horses.3,4 Reactivation after experimental infection can be trigged by administration of dexamethasone.13 Factors influencing reactivation of the virus and the importance of reactivated infections in dissemination of infection and induction of disease is unknown, but is likely important as for other equid herpesviruses.

It appears that foals are infected at a young age and that infection is persistent into adulthood.5,6,11 EHV-2 can be isolated by 25 days of age from foals that were seronegative at birth and there is a progressive increase in virus neutralization from 1 to 5 months of age.6 Viral shedding is persistent until development of high antibody titers at 6–9 months of age.5

PATHOGENESIS
The pathogenesis of EHV-2 has not been defined. However, it is apparent that infection occurs at a young age, as each as several weeks of age, and becomes latent in lymph nodes, especially those draining the respiratory tract, peripheral blood mononuclear cells, and nervous tissue including the trigeminal ganglion. As with EHV-1, there is evidence that EHV-2 causes immunosuppression14 and it is speculated that this might play a role the development of other infections, including pneumonia associated with Rhodococcus equi or other bacteria.5

CLINICAL FINDINGS
EHV-2 or equine cytomegalovirus causes a long-term infection in foals, some of which develop clinical signs of purulent nasal discharge, fever and lymphadenopathy in a syndrome which lasts about 1 week. Affected animals rarely die although deaths of foals from pneumonia have been recorded.5,6,8 EHV-2 was isolated from 20 of 30 foals with signs of lower respiratory disease including fever, abnormal lung sounds and radiographic abnormalities.5 Bacteria were isolated from tracheal aspirates of 29 of these foals.

EHV-2 is statistically associated with keratoconjunctivitis in horses of varying ages.5
antibody specific for EHV-2, and is useful to detecting new infection in foals.\(^\text{15}\) Identification of the virus in nasal swabs, blood Buffy coat or fetal tissue by culture or a PCR test provides confirmation of infection.\(^\text{16}\)

**NECROPSY FINDINGS**

Necropsy findings for diseases associated with EHV-2 infection are poorly reported. Two foals that died of respiratory disease associated with EHV-2 infection had pneumonia, chronic pharyngitis and lymphoid depletion in the thymus and spleen.\(^\text{9}\)

**DIFFERENTIAL DIAGNOSIS**

Differential diagnosis includes other causes of respiratory disease in horses (Table 16.4).

**TREATMENT**

There is no specific treatment for the diseases associated with equine herpesvirus-2 infection. Antibiotics are often administered to horses with respiratory tract disease to prevent or treat secondary bacterial infection.

**CONTROL**

Control is difficult given the ubiquitous nature of infection and uncertain importance of disease associated with EHV-2. There is currently no commercial vaccine to prevent infection or disease associated with EHV-2.

**REFERENCES**

**ETIOLOGY**

Viral arteritis of horses, donkeys and mules is associated with an arterivirus, formerly classified as a non-arthropod borne togavirus but now recognized as a member of the coronavirus-like superfamily.\(^\text{1}\) The virus is single-stranded RNA. There is considerable genomic variation among isolates with EAV of North American and European origin clustering in geographically distinct viral clades.\(^\text{2}\)

**EPIDEMIOLOGY**

**Occurrence**

Serologic evidence of infection by equine arteritis virus (EAV) is found in horse populations in North and South America, Europe, Africa, Asia, and Australia.\(^\text{7}\) Recent disease outbreaks have been identified in North America, Britain, Spain, Italy, France, Poland, The Netherlands, South Africa, and Germany.\(^\text{8}\)

It is probable that the disease is now present in most countries with substantial populations of horses. International shipment of horses and frozen semen contributes to the spread of the EAV.\(^\text{8}\)

The proportion of seropositive horses varies considerably among populations, with there being marked differences among breeds. Overall, 2% of horses in the United States are seropositive to EAV (serum neutralization titer >1:4) with 8.4% of horse operations having seropositive horses.\(^\text{9}\)

Twenty-five percent of operations whose principal activity was breeding had at least one unvaccinated seropositive horse, whereas 4% of racing operations had at least one unvaccinated seropositive horse.\(^\text{2}\) The prevalence of titer to EAV is higher in mares and in horses used for breeding.\(^\text{3}\)

The frequency with which horses in the United States have serum titers >1:4 varies with breed with 24% of Standardbreds, 4.5% of Thoroughbreds, 3.6% of Warmbloods and 0.6% of Quarter horses being seropositive.\(^\text{3}\)

Approximately 19% of Warmblood horses imported into the United States have antibodies to EAV, with horses from Germany and the Netherlands having the highest prevalence (21 and 25% respectively).\(^\text{10}\)

Between 55–93% of Warmblood and Lipizzan breeds in Austria have serologic evidence of exposure to EAV.\(^\text{11}\)
America has been associated with importation of infected stallions or semen. Horses of all age groups are susceptible. The disease spreads rapidly in a group of susceptible horses, and although the course of clinical disease is short, an outbreak in a group of horses may persist for a number of weeks. Naturally acquired infections in newborn foals can occur as an outbreak and cause severe disease.

Origin of infection and transmission

EAV is spread in two ways:

1. **Horizontal transmission** of virus by predominantly nasal fluid, but also by urine, feces, lacrimal fluid and vaginal discharge of infected horses.

2. **Venereal transmission** from stallions to susceptible (seronegative) mares.

**Horizontal transmission** through infected nasal discharge and body fluid is effective and is the means of disease spread in outbreaks in racing stables, and among mares and foals at breeding farms. Virus is found in the respiratory secretion for 7–14 days and in other tissues for 28 days. Close contact between horses is probably required for transmission of the virus – it has been reported to spread after contact of horses across a fence. Duration of viability of the virus in the environment has not been reported, but the potential for spread of infection on fomites includes clothing and tack should be considered when dealing with an outbreak.

**Venereal transmission**: Stallions are infected by horizontal transmission of the virus, subsequently excrete the virus in semen and infect susceptible mares at the time of mating. Clinically normal stallions are also capable of transmitting the virus horizontally to other stallions in a breeding operation, demonstrating the potential for horizontal spread of infection from stallions in the absence of clinical disease or sexual contact. Between 30 and 60% of infected stallions excrete the virus in semen for weeks to months. Some stallions excrete virus for years, and lifelong infection and virus excretion can occur. Prolonged infection of stallions is associated with mutation of the virus and secretion by the stallion of viral strains that vary over time. However, disease resulting from transmission of infection from a stallion to a mare, and subsequent spread of infection to other horses, is associated with a single viral strain. In other words, stallions can excrete a variety of strains of the virus during their life, but outbreaks of disease are associated with a single viral strain; multiple viral strains are not detected during outbreaks of disease.

Prolonged excretion of the virus in semen is likely important in the maintenance of the virus in populations of horses. Introduction of a **persistently infected stallion** into a naive population or insemination of seronegative mares with semen from an infected stallion have been implicated as the cause of outbreaks of viral arteritis. The carrier stallion infects mares at mating, the mares develop disease and shed virus in nasal and other body fluids and infect in-contact susceptible horses and foals by horizontal transmission.

**Immunity**

Vaccination or recovery from natural infection results in the development of a strong serum antibody virus neutralizing response which is believed to be important in clearance of the virus and resistance to infection. Naive, pregnant mares infected by horizontal transmission may abort or, less commonly, give birth to infected foals that subsequently die.

Foals of immune mares are resistant to infection, and viral neutralization antibodies are present in mare’s colostrum and foal’s serum after sucking, with persistence of the antibodies to the age of 2–6 months in the foals. Persistence of passive immunity in foals has important implications for resistance to infection and for timing of administration of modified live vaccines.

**Economic importance**

The chief impact of the disease on breeding farms is the loss of foals through abortion and the cost of quarantine and control measures. The systemic illness may be severe, but the mortality rate is low. During outbreaks at race tracks the economic impact is a result of lost opportunities for training and racing sick or convalescing horses, and the effect of quarantine and control measures. Additional costs are incurred by the inconvenience and cost of vaccinating mares to be bred to stallions infected with the virus and import regulations controlling movement of horses and semen including the inability to export mares, fillies and non-carrier stallions that are seropositive (perhaps as a result of vaccination), and the limited opportunities for export of semen from infected stallions or export of the stallions themselves.

**PATHOGENESIS**

The pathogenesis of disease associated with horizontal transmission of EAV has been elucidated. After inhalation of the virus it binds to the respiratory epithelium and infects alveolar macrophages and is detectable in bronchial lymph nodes by 48 hours after infection. Three days after infection the virus is detectable in circulating monocytes with subsequent systemic distribution of infection. The virus localized in vascular endothelium and medial myocytes by days 6–9 and there is significant damage to blood vessels by day 10. The virus infects renal tubular epithelium and can persist there for up to 2 weeks. Medial necrosis of blood vessels might cause anoxia of associated tissues. Virus is not detectable in any tissue by 28 days after infection, with the exception of accessory sex glands in intact male horses.

Abortion is caused by a severe necrotizing myometritis and presupposes consequent reduction in fetal blood flow. The absence of lesions in the fetus, although the fetus is sometimes infected with the virus.

**CLINICAL FINDINGS**

Infection by EAV is usually **clinically inapparent**, especially after venereal infection of mares. Abortion is not necessarily associated with clinical disease in the mare. Systemic disease is usually mild to moderate and self-limiting with recovery in 5–9 days in the vast majority of horses.

Systemic disease is characterized by an incubation period of 1–6 days followed by the appearance of fever (39–41°C, 102–106°F). A serous nasal discharge which may become purulent and be accompanied in some horses by congestion and petechiation of the nasal mucosa, urticaria, conjunctivitis, excessive lacrimation developing to purulent discharge, keratitis, palpebral edema, and blepharospasm. Opacity of the aqueous humor and petechiation of the conjunctiva may also occur. Signs of pulmonary disease, such as respiratory distress and coughing are attributable to pulmonary edema and congestion, but are uncommon. The appetite is reduced or absent and, in severe cases, there may be abdominal pain, diarrhea and jaundice. Edema of the limbs is common and more marked in stabled horses than those at pasture. In stallions, edema of the ventral abdominal wall may extend to involve the prepuce and scrotum. Depression is usual and varies in degree with the severity of the syndrome. The disease is acute and severe, and deaths may occur without secondary bacterial invasion. In these cases dehydration, muscle weakness and prostration develop quickly. It must be emphasized that the disease may be much milder than that described above.

**Clinical disease in neonatal foals** is characterized by fever, profound depression, weakness, limb and facial edema, and respiratory distress. Severely affected foals usually die. Foals can be affected at birth, or be born apparently normal and develop disease 1–19 days after birth. Abortion occurs within a few days of the onset of clinical illness, although it
is not usually associated with clinically apparent disease. Abortions may occur in 10–60% of at-risk mares during an outbreak and during the 3rd–10th months of gestation. Abortion occurs 12–30 days after exposure. The abortion is not foreshadowed by premonitory signs, and the placenta is not retained.

**CLINICAL PATHOLOGY**

**Hematological examination** of adults and foals during the acute phase of the systemic disease is characterized by leukopenia and thrombocytopenia.

Serological confirmation of infection is achieved using complement fixation, serum neutralization and ELISA tests. Serum conversion occurs within 1 week of infection, and demonstration of a rising antibody titer, based on acute and convalescent serum samples, or seroconversion is considered evidence of recent infection. False-positive results for the virus neutralization test have occurred using OIE prescribed rabbit kidney (RK-13) indicator cells when testing serum from horses vaccinated with an EHV-1/4 tissue cultured derived vaccine. The false-positive results are likely a result of vaccine-induced antителlar antibody response against the RK-13 cells.

**Virus isolation** from blood, body fluids, fetal or placental tissue is readily achieved during the acute phase of the disease. Appropriate samples for virus isolation include nasopharyngeal or conjunctival swabs and anticoagulated whole blood (heparin, EDTA or citrate are suitable fluids, fetal or placental tissue is readily achieved during the acute phase of the disease. Appropriate samples for virus isolation include nasopharyngeal or conjunctival swabs and anticoagulated whole blood (heparin, EDTA or citrate are suitable fluids, fetal or placental tissue is readily isolated from the spermatic fluid, and is readily isolated from the spermatic fluid of infected stallions and is readily isolated from the spermatic fluid of the semen. A nested PCR can detect the presence of virus in naturally infected semen at concentrations as low as 25 plaque forming units per mL, with a specificity of 97% and a sensitivity of 100%, and may be useful for the rapid diagnosis of EVA shedding stallions.

Antemortem diagnosis of EAV disease can be achieved by examination of skin samples using monoclonal antibody immunoperoxidase histochemistry. Examination of skin samples obtained by biopsy reveals edema and vasculitis and presence of intracytoplasmic EAV antigen.

**Necropsy findings**

Cross lesions include edema of the eyelids and petechiation of the upper respiratory tract, and the serosal of the abdominal and thoracic viscera. There is an abundant serofibrinous pleural and peritoneal effusion with generalized edema of the lungs, mediastinum, and abdominal mesenteries. A hemorrhagic enterocolitis, as well as hemorrhage and infarction in the spleen may be noted. Characteristic histological changes are found in the small arteries and include fibrinoid necrosis of the tunica media and karyorrhexis of the infiltrating leukocytes. Fluorescent antibody or immunohistochemical staining demonstrates viral antigen within the endothelial cells of these blood vessels. An immunoperoxidase method has also revealed viral antigen within endothelial cells and macrophages of an aborting mare and her fetus and within skin biopsies of animals exhibiting a maculopapular rash. Sero­logical tests performed on samples collected at necropsy can also be used to confirm that exposure to the virus has occurred.

The virus can be isolated from the lung and spleen of aborted fetuses, but no consistent, specific lesions are present. Necro­tizing arteritis, similar to that in the mare, may be detectable.

**Samples for confirmation of diagnosis**

- Virology – chilled lung, spleen and thymus (VI, PCR, FAT)
- Serology – heart-blood serum or fetal throracic fluid (VN, ELISA, CF)
- Histology – fixed lung, spleen, adrenal, jejunum, colon and heart (LM, IHC).

**DIFFERENTIAL DIAGNOSIS**

Definitive diagnosis is based on isolation of EAV from affected cases, or the demonstration of seroconversion or an increase in serum antibody titer.

The systemic disease must be differentiated from that associated with EHV-1 or EHV-4 infection, equine influenza, strangles (see Table 16.4), infection with Getah virus in Japan, equine infectious anemia, African horse sickness, and purpura hemorrhagica.

Abortion should be differentiated from that associated with EHV-1, Salmonella abortusequi, leptospirosis, mare reproductive loss syndrome, and congenital malformations.

Similar disease in neonates can be associated with EHV-1, immaturity or premature birth, and bacterial septicaemia.

**TREATMENT AND CONTROL**

There is no specific treatment for equine viral arthritis. Most horses recover without specific care. Severely affected foals require intensive care.

Control of EAV infection is based on the strong immunity induced by natural infection or vaccination with a modified live virus, and an understanding of the role of carrier stallions in the disease. The following practices are suggested:

1. Isolate all new arrivals (and returning horses) to farm or ranch for 3 to 5 weeks
2. If possible, segregate pregnant mares from other horses
3. Blood test all breeding stallions for EAV antibodies
4. Check semen of any unvaccinated, antibody-positive stallions for EAV to identify carriers before breeding
5. Once tested negative for EAV antibodies, vaccinate all breeding stallions annually
6. Physically isolate any EAV carrier stallions
7. Restrict breeding EAV carrier stallions to vaccinated mares or mares which test positive for naturally acquired antibodies to the virus
8. Vaccinate mares against EVA at least 3 weeks prior to breeding to a known carrier stallion
9. Isolate mares vaccinated for the first time against EVA for 3 weeks following breeding to an EAV carrier stallion
10. In breeds or areas with high rates of EAV infection, vaccinate all intact males between 6 to 12 months of age.

**Testing of mares and stallions** permits identification of serologically negative, and therefore at-risk, animals. Seronegative mares should not be mated with infected stallions nor inseminated with fresh or frozen semen from infected stallions because of the risk of transmission of infection to the mare. Seropositive mares, or mares that have been vaccinated at least 3 weeks, can safely be bred to stallions that have serological evidence of infection. Seropositive mares should be separated from seronegative mares for at least 3 weeks after mating to a seropositive stallion. Seropositive stallions that have not been vaccinated should have their semen cultured to determine if they are excreting the virus. Stallions excreting virus in their semen should be kept isolated from susceptible horses but can be bred to seropositive mares, as described above. Because the virus survives cooling and freezing, similar principles should be applied to the use of artificial insemination in horses. One control program requires that all stallions be vaccinated with a modified live virus vaccine 28 days before the beginning of each breeding season. Vaccination with a modified live virus vaccine induces strong immunity, although revaccination is necessary to insure continuing immunity. The vaccine protects mares exposed to stallions shedding the virus in semen and has been used to control outbreaks of the respiratory form of the disease at racetracks. The modified live virus vaccine is
regarded as safe, except that there is mild fever and leukopenia, and evidence that the vaccine virus replicates in the vaccinated. A killed virus vaccine has limited availability and its efficacy in the field has not been reported. Antibodies induced by the vaccine cannot be differentiated from those resulting from natural infection, a situation that may be problematic when import restrictions require the horse to be seronegative, presumably as proof of lack of exposure to virulent EAV.

Vaccination of foals from immune mares results in good protection provided that the timing of vaccination is delayed until maternal antibodies to EAV are no longer present in the foal.

**REVIEW LITERATURE**

**REFERENCES**

**ETIOLOGY**

Equine influenza is associated with infection by equine influenza A/H7N7 (previously referred to as equine influenza A1) or equine influenza A/H3N8 (previously referred to as equine influenza A2) viruses, members of the influenza virus genus of the family Orthomyxoviridae. Of the two serologically distinct subtypes, all reported outbreaks in the past two decades have been associated with strains of EIV-A/H7N8. There are no reports of disease associated with EIV-A/H7N7 in the past 25 years and reports of seroconversion might be related to use of vaccines containing EIV-A/H7N7 antigen. There are no reports of other influenza viruses, such as the H1N1 avian virus, causing disease in horses, although the avian-like influenza A/II/Jilin89 (H3N8) caused severe disease and high mortality among horses in China in 1989. Equine influenza H3N8 virus can infect dogs and cause serious disease and death.

Currently, two major lineages of EIV-H3N8 circulate in horse populations – a Eurasian lineage and an American lineage. The terms Eurasian and American do not denote geographical isolation of these lineages, and viruses of American lineage circulate in Europe and North America, although to date only one strain of Eurasian lineage is known in North America. The American lineage has further division of the viruses into three distinct lineages (South American, Florida, and Kentucky) with the predominant lineage varying from year to year with evidence of cycling.

Cycling is the predominance of one lineage one year, and the other lineage in the subsequent year, with reversion to the initial lineage in the third year, and so on. This is believed to be a mechanism for viral perpetuation, allowing avoidance of eradication of the virus by changing the immunological target from year to year without viral evolution. The predominating virus lineage or strain varies from year to year and from region to region. The important point is that there is continual change in the viral strain in some populations of horses and that constant monitoring of viral strains is vital for appropriate composition of vaccines and for molecular epidemiology. For instance, the majority of viruses from Europe (France, Italy and the UK) and North America characterized antigenically and/or genetically between January 2003 and April 2004 were of the American lineage. Based on hemagglutination inhibition (HI) testing most viruses isolated in Europe, represented by A/equine/Newmarket/5/03, were antigenically closely related to the vaccine strains, A/equine/Newmarket/1/93 (American lineage), A/equine/Kentucky/97 and A/equine/Kentucky/98 (American lineage). Viruses recently isolated in South Africa and the USA were distinguishable from these three vaccine strains and were more closely related to A/equine/South Africa/4/03. The South African strain was identical to an American lineage strain originally isolated in Wisconsin in 2003 (A/Equine/Wisconsin/1/03). The American lineage viruses circulating in Europe during 2002, represented by A/equine/Lincoln/1/02, and were distinguishable from the prototype vaccine strain A/equine/Newmarket/2/93. The European lineages viruses circulating in 2002 were heterogeneous in their antigenic and genetic characteristics. Information about EIV strains changes constantly and is available at the equiflunet website.

The existence of lineages and strains of virus is important in the epidemiology of the disease because the antigenic differences among strains can be sufficient to prevent cross-protection provided by natural infection or vaccination. Cross-protection refers to the ability of one antigen (virus strain) to produce immunity in the horse against infection with another type of antigen (virus strain). Infection or challenge with the same type of antigen is referred to as homologous challenge, whereas that with a different antigenic type is referred to as heterologous challenge. Strains of influenza virus circulate between and among populations of horses, with more than one strain of virus circulating at any one time in some horse populations, although individual disease outbreaks are associated with a single viral strain. Many, but not all, of these virus strains are constantly evolving and the viruses is necessary for perpetuation of cycles of infection.

---

**EQUINE INFLUENZA**

**Synopsis**

**Etiology** Influenza virus H3N8 (previously A/equine) of two lineages and numerous, evolving strains. Historically, H7N7 virus.

**Epidemiology** Short incubation period and highly contagious nature of the virus result in explosive outbreaks of disease. Viral shedding by subclinically affected horses is important for introduction of infection to populations. Prolonged carrier state is not recognized.

**Clinical signs** Upper respiratory disease complicated by pneumonia. Abortion is not a feature of the disease.

**Clinical pathology** None characteristic.

**Lesions** Rhinitis, pneumonitis. Rarely causes death.

**Diagnostic confirmation** Demonstration of virus in nasopharyngeal swab either by culture, ELISA, PCR, or membrane bound immunosassay.

**Treatment** Supportive care. There is no specific treatment.

**Control** Vaccination, often every 4 months; quarantine and hygiene.
through the emergence, or reemergence by cycling, of heterologous strains.\textsuperscript{5,11} Evolutionary stasis, the continued circulation of older strains of virus, occurs and has importance for vaccine composition.\textsuperscript{11} However, emergence of new strains is common and of great importance for control of the disease. Evolution of strains of equine H3N8 virus occurs through antigenic drift. \textbf{Antigenic drift}, the accumulation of point mutations in the gene coding for the major surface protein hemagglutinin, occurs continuously in virus circulating in horse populations. Antigenic drift occurs most rapidly in hemagglutinin protein but also occurs in M and NS genes.\textsuperscript{12} Antigenic drift, by producing heterologous viral strains, contributes to the continuing susceptibility of horses to infection and the reduced efficacy of some vaccines.

Influenza virus is an RNA virus that has eight segments to its genome which encodes ten proteins. The hemagglutinin and neuraminidase proteins are used for antigenic characterization of virus strains. Mutations in these genes or poor fidelity RNA copying results in changes in amino acid composition of viral proteins that may be detected by serological tests (see 'Clinical Pathology') and that might have, as discussed above, important consequences for infectivity and pathogenicity of the virus. \textbf{Antigenic shift} is an event in which there is a dramatic alteration in the viral genome occurring by reassortment of viral genes during coinfection of a cell by two different types of virus (for example infection of a pig by both avian and human influenza viruses). Antigenic shift, which has not been documented for influenza viruses infecting horses, has the potential to produce new viruses with markedly different host infectivity and pathogenicity to either parent virus.

\textbf{EPIDEMIOLOGY}

\textbf{Occurrence}

Worldwide, the only large horse populations in which influenza virus infection does not occur are in Australia and New Zealand. Widespread use of aircraft to move horses between countries in short periods has increased the spread of equine influenza viruses, as exemplified by the 2003 outbreak of equine influenza in horses in South Africa associated with a virus from North America, and an earlier outbreak in Hong Kong. In both cases virus was introduced by imported horses.\textsuperscript{8,13,14}

\textbf{Epidemics} of equine influenza have occurred in Europe or North America in 1956 (H7N7), 1963 (H3N8), 1969, 1979, and 1989, although this does not represent a comprehensive listing of large scale outbreaks.\textsuperscript{3,5,6} Epidemics affecting >1 million horses occurred in China in 1989 (associated with the novel H3N8 Jilin virus) and 1993/1994 (associated with a conventional H3N8 virus closely related to 1991 European isolates).\textsuperscript{18} Epidemics in Europe and North America have been associated with introduction of a novel virus (for example the 1963 appearance of H3N8 virus in Miami) or antigenic drift of existing viruses and resultant inefficacy of extant vaccines.\textsuperscript{15}

\textbf{Localized outbreaks} of disease in stables or race courses occur almost annually in countries in which the disease is endemic, likely related to movement of horses into the training and racing populations, with subsequent introduction of virus and development of disease in at risk horses (see 'Animal Risk Factors'). Disease associated with equine influenza virus usually occurs as outbreaks associated with the introduction of virus into a population of susceptible horses. Virus may be introduced by clinically affected horses or, more commonly, by horses that are not noted to be clinically ill. Vaccinated horses may become infected and shed influenza virus while not becoming ill, especially if vaccinated with heterologous strains, and this is likely a common method of introduction of virus into susceptible populations.

Outbreaks of influenza virus infection may cause clinical disease in nearly all (98%) horses in a susceptible population, although in populations of horses of mixed age and with varying serum titers to equine influenza the morbidity rate may be much lower (16–28%).\textsuperscript{15} The incidence of disease in one race track population was approximately 130 cases per 1000 horses at risk per month,\textsuperscript{16} although this rate likely varies widely among outbreaks. The mortality rate is usually very low (<1%) with most deaths associated with secondary bacterial infections. However, a recent outbreak of disease in China associated with a novel H3N8 (Jilin virus) strain was associated with a morbidity rate of 80% and mortality rate of 20–35%.\textsuperscript{2}

The disease in populations of vaccinated or previously exposed horses is associated with a lower morbidity and mortality, and slower spread, due to the milder disease induced by influenza virus infection of immune or partially immune horses. In an outbreak among vaccinated racehorses in Hong Kong, 75% of horses had serological evidence of infection, 37% had clinical signs of infection, and 0.2% died.\textsuperscript{14} Horses imported from Australia and New Zealand, where the disease does not occur, had a morbidity rate of 52%, while horses from the northern hemisphere had a morbidity rate of 20%, likely reflecting the effect of previous exposure to influenza virus or repeated vaccination.\textsuperscript{14}

The profile of an epidemic can vary from explosive with a large proportion of a small group of susceptible horses housed in close proximity, such as a small band, developing clinical disease within 24–48 hours, to much more prolonged outbreaks lasting several weeks in larger groups of horses of varying susceptibility housed in multiple barns. During larger outbreaks among horses of varying susceptibility there is a characteristic three phase pattern.\textsuperscript{18} The first stage is associated with the first cases of disease and slow spread over 10–14 days. This stage is followed by one of rapid spread of the disease to horses clustered in stalls around horses affected during the first phase of the outbreak. The third phase is characterized by declining numbers of cases.\textsuperscript{18}

\textbf{Origin of infection and transmission}

Equine influenza virus is relatively susceptible to environmental conditions, and during an outbreak infection must originate from an infected horse although the proximate source of virus can be contaminated equipment or other fomites.

\textbf{Transmission} of equine influenza virus occurs by direct contact, inhalation of aerosols of infected material, and on fomites. Survival of the virus on clothing and surfaces, including vehicles used to transport horses shedding the virus, can result in transmission of infection in the absence of horse to horse contact.\textsuperscript{8}

\textbf{Fomite transfer} on veterinary clothing, equipment or vehicles was likely responsible for the spread of infection from quarantined horses in both South African outbreaks.\textsuperscript{3,9} However, in most instances, horses are infected by other horses that are in close proximity or have physical contact, for instance exercise ponies (horses or ponies used to accompany race horses from the stable to the track in preparation for racing or training gallops) or stable mates.\textsuperscript{17} Aerosol spread occurs over distances of 35 meters, possibly further, and is enhanced by the frequent coughing characteristic of the disease. Equine influenza virus in aerosols survives longer (24–36 hours) than human or porcine strains (15 hours).

Clinically affected horses excrete more virus than do horses in which the infection is apparent. The duration of infectivity of clinically affected horses is 3–8 days and with the short incubation period of 2–3 days combine to produce the potential for a very rapid new infection rate and a characteristic explosive outbreak.

\textbf{Risk factors}

\textbf{Animal factors}

All age groups of horses, including newborn foals, are susceptible. The greatest
Risk appears to be between the ages of 2 and 6 months,\textsuperscript{20} serum levels of passively acquired antibodies being lost by foals at 2 months of age.\textsuperscript{3,7} A recent survey of 3,800 horses in the United States revealed that only 20.2\% of horses aged 6 to 12 months had a detectable influenza antibody titer (HI), as compared to 89.0\% of horses aged 20 years or more.\textsuperscript{25} The percentage of horses that had a high equine influenza antibody titer increased as the horse's age increased such that 45–51\% of horses older than 5 years had high titers. This observation is consistent with most cases of the disease occurring in 2-year-old or younger horses, probably because older horses are immune through either natural exposure or vaccination. Thoroughbred and race horses <2 years were 5–8 times more likely to develop influenza than were horses ≥5 years of age in a well characterized series of outbreaks.\textsuperscript{17} Seronegativity to a H3N8 virus (Saskatoon/90) was associated with a 13–38 fold increase in likelihood of developing influenza, independent of the effect of age.\textsuperscript{17} It is probable that outbreaks occur as a result of a natural accumulation of young animals which have not been previously exposed, the co-mingling of these susceptible animals with older infected ones at race and show meetings, and to the significant level of antigenic 'drift'. This capacity of the virus to change slightly and continuously in antigenic composition leads to the frequent appearance of new strains which are likely to breach existing natural and induced immunological barriers.

Outbreaks can occur at any time of year, and their timing probably depends on husbandry and management practices, such as yearling sales, transport of horses for racing and sale, and movement of show and breeding animals. These events often provide the combination of a population of susceptible animals housed in crowded, poorly ventilated barns that facilitate transmission of the virus.\textsuperscript{23}

**Immunity** depends on the means of exposure (vaccination or natural infection), the strain of the virus, and the time since exposure. After infection, protective immunity to homologous strains of the virus is present and persists for 1 year, possibly up to 2 years. Field studies of disease outbreaks indicated that the concentration of antibodies in serum that provide some resistance to disease might be less than that suggested from experimental studies.\textsuperscript{17} Protective immunity induced by natural infection is characterized by production of IgA in nasal secretions and IgG\textsubscript{a} and IgG\textsubscript{b} in serum, whereas administration of an inactivated, alum-adjuvanted commercial vaccine induces only a serum IgG(T) response that is not protective against challenge.\textsuperscript{24} Immunity after vaccination lasts for a much shorter period of time, 3–4 months, and is specific for the subtypes, and their strains, of virus included in the vaccine. Immunity following infection or vaccination is less protective against infection by a heterologous strain.\textsuperscript{25} Similarly, vaccination exposure to a heterologous virus may induce only a poor anamnestic immune response.\textsuperscript{23}

These observations are consistent with the concurrent circulation of multiple viral strains influenza virus in horse populations, and the cycling of virus strains causing disease in consecutive years.\textsuperscript{5}

**Management factors**

Housing of large numbers of horses in close contact, or in enclosed environments such as large barns or stables, provides optimum conditions for facilitating contact and aerosol spread of the virus. Shed barns, which characteristically have poor ventilation and greater stocking density than pole barns, are associated with a 4-fold increase in risk of influenza.\textsuperscript{17}

Presence of small numbers of horses with access to large numbers of at risk horses might impact the course of an epidemic. Track ponies, which have close contact with large numbers of horses on a daily basis, are important in spread of influenza in racing barns.\textsuperscript{17}

**Economic importance**

Influenza causes minimal loss through death of horses, but it causes much inconvenience in racing stables because it occurs in explosive outbreaks and affected horses have to be kept out of work. Such outbreaks have the capacity to close down the racing industry in a country for a period of months.\textsuperscript{14} An additional cost is incurred because of restrictions on international movement of horses and associated quarantine periods.

**Zoonotic potential**

Equine influenza A viruses can infect humans although such infections are unusual and subclinical.\textsuperscript{25}

**PATHOGENESIS**

The disease is principally one of inflammation of the upper respiratory tract, although pulmonary lesions are common in adult horses and the disease can cause severe, fatal pneumonia in foals.\textsuperscript{26,27} The virus is inhaled, attaches to respiratory epithelial cells with its hemagglutinin spikes, fuses with the cell, and is released into the cytoplasm where it replicates. New virions are released from the cell surface and infect other cells or are expelled into the environment. Initial viral infection and replication occurs mainly in the nasopharyngeal mucosa, but by 3–7 days after infection, virus can be recovered from cells throughout the respiratory tract. Infection of the respiratory mucosa results in death of epithelial cells, inflammation, edema, and loss of the protective mucociliary clearance. Death of cells is a result of influenza virus-induced apoptosis of respiratory epithelial cells and local and systemic increases in interferon and interleukin-6.\textsuperscript{26,29} Proliferation by opportunistic bacteria, commonly *Streptococcus zooepidemicus*, occurs because of the disruption of normal clearance mechanisms, and can exacerbate the inflammation and cause bronchopneumonia. Viremia, if it occurs, is mild and brief, although it may be related to some of the systemic signs of the disease. Some speculate that myocarditis, myositis and encephalitis occur occasionally in response to influenza virus infection, but definitive proof is lacking.\textsuperscript{23} Influenza virus has not been isolated from tissues other than those of the respiratory tract.\textsuperscript{23}

Enteritis was reported in horses in the 1989 Chinese outbreak (Jilin/89), but is not reported for disease associated with conventional virus strains.

**CLINICAL FINDINGS**

Outbreaks of equine influenza are characterized by a sudden onset and rapid spread of disease. Typically, in a large group of susceptible horses the incidence of the disease peaks about 1 week after the first case is noticed and new cases do not develop after 21–28 days.\textsuperscript{14,17,30} The disease may have an attenuated clinical course in a population of vaccinated or previously exposed horses. The milder disease in immune animals may be clinically indistinguishable from upper respiratory diseases associated with other common agents such as EHV-4, equine rhinitis virus and arteritis virus.

Clinically, the disease starts with a fever (38.5–41°C, 101–106°F) after an incubation period of 24–72 hours. Horses may be depressed, refuse feed, and reluctant to move. The dominant sign is cough, which is dry and hacking in the beginning and moist later, and which commences soon after the temperature rise and lasts for 1–3 weeks. It is easily stimulated by manual compression of the upper trachea. During the early stages of the disease, nasal discharge is not a prominent sign and, if it occurs, is watery. There is no marked swelling of the submaxillary lymph nodes but they may be painful on palpation in the early stages of the disease, especially in younger horses. Limb edema or swelling is unusual in horses with influenza. Abnormal lung sounds, characterized by crackles, wheezes, and increased intensity of normal breath sounds, is characteristic.
sounds may be apparent in both uncomplicated disease and in horses with secondary bacterial pneumonia. Ultrasonographic examination of lungs of horses with influenza, even clinically mild disease, reveals pulmonary consolidation, fluid bronchograms, and peripheral irregularities. Tracheal aspirates are neutrophilic, yield heavy growth of *S. zooepidemicus*, and are consistent with bronchitis and pneumonia. Horses, unwise, forced to exercise have reduced endurance. Horses that are protected against environmental stress pursue an uncomplicated course with most horses have complete recovery in 7–14 days, although a mild cough can persist for weeks.

The above is a description of the classical disease. However, in outbreaks there is a range of disease severity. Mucopurulent nasal discharge is observed in 75–90% of horses, cough in approximately 60%, fever in 20–50%, inappetence in 20–30%, and signs of depression in 20–40%. Undoubtedly, the proportion of horses showing each of these signs will vary from outbreak to outbreak depending on the age and susceptibility of horses in the population, among other factors.

**Complications** and a more severe disease occurs in a small number of horses. Horses that are worked, transported, or exposed to adverse climatic conditions can experience a worsening of the cough, and severe bronchitis, pneumonia and edema of the legs may develop. Complications are usually associated with secondary bacterial infection, usually *Strep. zooepidemicus*, that results in a mucopurulent nasal discharge, persistent fever, and markedly abnormal lung sounds. Icterus, encephalitic signs, incoordination and myoglobinuria are reported as rare complications. Electrocardiographic abnormalities have been reported in horses with influenza, and were attributed to myocarditis. However, there is no objective evidence of myocarditis secondary to influenza infection of horses nor is there a clear association between influenza infection and electrocardiographic abnormalities.

A more severe form of the disease, associated with an antigenically distinct strain of equine influenza 2, is reported from China. The mortality rate is 35%, and death is due to pneumonia and enteritis.

A severe form of the disease is also reported in young foals. Foals develop fever, severe respiratory distress and acute interstitial pneumonia that is commonly fatal. The disease is not invariably associated with failure of transfer of passive immunity.

**CLINICAL PATHOLOGY**

There are no characteristic changes on hematologic or serum biochemical examination of horses clinically affected by equine influenza virus infection.

**Confirmation of the diagnosis** of infection by equine influenza virus is achieved through virus isolation, indirect demonstration of virus in nasopharyngeal swabs, and/or serology. Measurement of antibody concentrations against the viral hemagglutinin antigen is important in determining susceptibility to infection, vaccine efficacy, and exposure – factors important in implementing control measures (see below). Documentation of seroconversion, a three- to four-fold increase in hemagglutination inhibition (HI) antibody titer, or a doubling in antibody titer measured by the single radial hemolysis test, in paired sera collection 14–21 days apart provides retrospective confirmation of the diagnosis. The single radial hemolysis test is more reproducible than the hemagglutination inhibition test and is the preferred test for determining concentrations of antibody against the hemagglutinin antigen. For the single radial hemolysis test virus is coupled to red blood cells that are then included in agarose Wells are punched in the agar plate filled with test sera. Influenza antibodies then cause lysis of red cells, with the diameter of the zone of hemolysis proportional to the concentration of the strain specific antibody in the serum. Antibodies against the non-structural protein (NS1) are detectable in horses after natural infection, but not after vaccination with an inactivated virus thereby permitting differentiation of immunologic responses to vaccination and infection.

However, because rapid identification of the cause of the outbreak is important when instituting control measures, timely demonstration of virus in nasopharyngeal swabs is desirable. Rapid demonstration of viral shedding can be accomplished by use of tests for rapid diagnosis.

**Directigen Flu A test** (Becton Dickinson) is a rapid test designed for use with humans, that identifies influenza viral nucleoprotein by a membrane-bound enzyme immunoassay. It has been validated for use in horses and is effective because of the conserved nature of the target antigen across influenza A strains. Results are available in as little as 15 minutes. The test had sensitivity of 83%, specificity of 78%, positive predictive value of 70%, and negative predictive value of 88% compared to virus culture. Sensitivity was 54%, but specificity and positive predictive value were 100% when compared with serological diagnosis. The low sensitivity compared to serology was ascribed to inadequate collection of nasopharyngeal swabs, or collection of samples when horses were not excreting virus. The high specificity and positive predictive value of the test mean that a positive result confirms the diagnosis of influenza infection. The relatively low specificity means that samples should be collected from a number of horses in various stages of the disease. Nasopharyngeal swabs should be collected by inserting a cotton gauze swab approximately 30 cm (12 inches) into the nostril or, preferably, nasopharynx of an adult horse and leaving it in place for 60 seconds. The swab should then be transferred to specialized transport media and shipped to the laboratory.

Other rapid diagnostic tests include the Flu OIA (Biosstar) assay for influenza A and B viral antigen. The test cross reacts with equine herpesvirus 2 and is therefore not useful for diagnosis of upper respiratory disease of horses. The test is more sensitive than the Directigen test, possibly because it detects nonviable viral material present in exfoliated epithelial cells. Other tests include the ZstatFlu (Zymetx), QuickVue Influenza (Quidel) and NOW Flu (Binax) assays, none of which have been validated for use in horses at the time of writing.

Use of rapid tests is not a substitute for virus isolation, which is important for typing of the isolate and subsequent epidemiological studies and vaccine applications. Isolation of the virus provides a definitive diagnosis.

Material for viral culture should be collected as early as possible during the illness and inoculated into the transport medium quickly. The transport medium should contain phosphate buffered saline, glycerol, and antibiotics, among other constituents.

Virus can be detected rapidly in clinical specimens by a reverse transcription PCR (RT-PCR) test for nucleoprotein gene, hemagglutinin gene of H3N8 viruses and hemagglutinin gene of H7N7 virus. RT-PCR and viral isolation are more sensitive than use of Directigen assay in detection of virus.

**NECROPSY FINDINGS**

Necropsy material is rarely available and the lesions in these fatalities are usually complicated by other pathogens. Histologically, a necrotizing bronchiolitis accompanies widespread pulmonary edema. Foals dying of acute respiratory distress associated with influenza infection have severe diffuse interstitial pneumonia which is characterized histologically by necrotizing bronchi and bronchiolitis and multifocal interstitial pneumonia.
Samples for postmortem confirmation of diagnosis

- Nasal swabs in viral transport media, and sections of lung and trachea should be submitted for virus isolation or demonstration by fluorescent antibody or PCR testing
- Formalin-fixed nasopharynx, trachea, and lung should be submitted for light microscopic examination.

DIFFERENTIAL DIAGNOSIS

See Table 16.4.

TREATMENT

Currently, there is no specific treatment of influenza virus infection of horses.

Amantadine is used in humans for prophylaxis and treatment of influenza infection in high-risk populations, and it has been investigated for use in horses. Amantadine administered intravenously caused transient neurologic abnormalities in experimental horses. Rimantadine (30 mg/kg PO q 12 hour) administered 12 hours before experimental inoculation of horses with equine influenza KY/91 mitigated signs of disease but did not eliminate viral shedding. However, the safety and efficacy of amantadine and rimantadine in horses with naturally occurring disease have not been demonstrated at this time. Until these issues are resolved, and because the infection has such a low case fatality rate, the use of these drugs in horses cannot be recommended.

Antibiotic treatment of uncomplicated cases is probably not warranted but horses that develop prolonged fever (greater than 5 days), signs of pneumonia, or a profuse mucopurulent nasal discharge should be treated with broad-spectrum antibiotics, such as potentiated sulfonamides (15-30 mg/kg, PO, IM, or IV, every 12 h), cefotiofur (22 mg/kg, IM, every 12 h), or procaine penicillin (20,000 IU per kg, IM, every 12 h) with or without gentamicin (6.6 mg/kg, IM, every 24 h). The usual cause of secondary bacterial infection is S. zooepidemicus, which is susceptible to penicillin.

Supportive treatment includes rest, provision of a dust-free environment and, on occasion, administration of non-steroidal anti-inflammatory drugs (NSAIDs). However, NSAIDs should be used judiciously, as their analgesic properties may mask signs of complications, such as pleuritis. Corticosteroids are contraindicated in the treatment of this disease. Cough suppressants are also contraindicated, as coughing is a normal protective mechanism that aids in the clearance of material from the airway. Muscylites can be administered but their efficacy is unknown. clenbuterol administration does not alter the course of the disease and is not recommended.

CONTROL

The fundamental aims of a control program are to:

- Increase the immunity of both individual animals and the population to infection
- Reduce the opportunities for spread of infection between horses
- Prevent the introduction of novel strains of the virus into a population.

These aims are achieved by vaccination, hygiene and quarantine.

Immunity and vaccination

Immunity to influenza through administration of inactivated vaccines can be assessed by measurement of serum antibody concentrations against hemagglutinin, using the single radial hemolysis test, whereas immunity gained through natural infection is independent of serum antibody concentration. However, serum antibody concentration is currently used as an indicator of susceptibility of individual horses to infection, and as a guide in the development and application of vaccination protocols, including monitoring of need for vaccination in individual horses. Serum antibody concentrations to hemagglutinin measured by single radial hemolysis are specific for the strain of virus and are strongly predictive for resistance to disease associated with that virus in both experimental and field challenge. Failure of a commercial inactivated virus multivalent vaccine to induce detectable increases in antibody concentration in Throroughbred race horses was associated with lack of protection against natural infection by a heterologous influenza virus. It is important to reiterate that resistance to disease after vaccination or natural infection is greatest for homologous virus and minimal for challenge by heterologous virus. Thus, horses with antibody concentrations protective to disease associated with homologous virus are susceptible to disease associated with heterologous virus.

Vaccines

A complete listing of current commercially available vaccines, the viral stains or antigens included, and the adjuvant used is available at the equifluent website. This site should be consulted for up to date information on equine influenza vaccines as this is a rapidly developing field. For instance, during the period January 2003 to April 2004, H3N8 viruses of the American lineage caused widespread outbreaks in Europe, with well-vaccinated horses frequently affected. Furthermore, viruses responsible for recent outbreaks in South Africa (2003) and circulating in North America were antigenically distinguishable from the currently recommended vaccine strains. On the other hand, viruses of the European lineage were associated with limited, more localized, outbreaks in Europe and were antigenically and genetically similar to some viruses circulating during 2002. Based on these observations, it is recommended that vaccines are updated to contain an A/equine/South Africa/4/03 (H3N8)-like virus (American lineage) and an A/equine/Newmarket/2/93 (H3N8)-like virus (European lineage). A/equin/Suffolk/89 and A/equin/Borlange/91, currently used vaccine strains, continue to be acceptable.

There are several forms of vaccine available including those that contain one of inactivated virus, modified live virus, hemagglutinin and neuraminidase subunits, or hemagglutinin proteins. Furthermore, the type of adjuvant varies among vaccines with carbomer, aluminum hydroxide, carbopel, saponin, immunestimulating complex (ISCOM), and various proprietary products (Meta-stim, PureVax) being used. A comparison of each vaccine is beyond the scope of this text, but several principles should be considered when selecting a vaccine: the vaccine should induce a measurable immune response and demonstrable by vaccines (and natural infection) to challenge by heterologous virus. Furthermore, the immune responses induced by administration of inactivated virus or subunit vaccines, which are primarily an increase in serum IgG(T) antibody titer, differ markedly from the immune responses to natural infection, which are production of IgA in nasal secretions and IgGa and IgGb in serum.

Multiple factors are important in determining the efficacy of a vaccine in protecting against disease. Factors include efficacy of the vaccine in stimulating an immune response, viral strains included in the vaccine amount of antigen in a dose of vaccine adjuvant, and timing and frequency of administration of the vaccine.
protection against disease (natural or experimental), it should contain pertinent viral strains, it should be safe, and it should be practical (i.e. readily administered).

Most vaccines are comprised of inactivated or subunits of virus combined with an adjuvant. Inclusion of an adjuvant is important in maximizing the immune response to vaccination. The important factor in vaccine composition is the inclusion of adequate amounts of antigen of pertinent strains of virus. H7N7 virus is no longer a cause of clinical disease and it should not be included in contemporary vaccines. Inclusion of antigen from both American and Eurasian lineages of H3N8 virus is essential, and vaccine composition should be regularly updated to reflect those viruses currently circulating in the horse population. The vaccine must include an adequate amount of antigen, measured by the single radial diffusion assay, preferably, the single radial hemolysis assay, as there is a clear relationship between dose of antigen and magnitude and duration of antibody response. There is increasing concern, and some evidence, that inclusion of multiple antigens in vaccines (for example, tetanus toxoid, equine herpesvirus, encephalomyelitis virus) reduces the efficacy of influenza vaccines. While this concern has yet to be proved conclusively, it should be borne in mind when formulating vaccine programs for horses at high risk of influenza.

A modified live virus vaccine is available in North America and has proven to be effective in experimental studies in preventing disease against heterologous virus challenge (both American and Eurasian lineages). Furthermore, the duration of protection is at least 6 months after completion of a course of vaccination. Vaccinated ponies had significantly lower clinical scores, smaller increases in rectal temperature, and shedding virus over fewer days than did the unvaccinated controls in response to challenge 6 months after vaccination. After challenge at 12 months, vaccinees had rectal temperatures, duration, and concentration of virus shed significantly reduced to that in unvaccinated animals. The results of this study showed that 6 months after a single dose of vaccine the duration and severity of clinical signs were markedly reduced amongst vaccinated animals exposed to a severe live-virus challenge. Appropriate use of this vaccine should lead to a marked reduction in the frequency, severity and duration of outbreaks of equine influenza in North America.

A live recombinant canary pox vector vaccine has been introduced in Europe. The vaccine uses the viral vector to introduce influenza hemagglutinin genes into host cells. The recombinant virus expresses the hemagglutinin gene of both A/eq/Newmarket/2/93 (European lineage) and A/eq/Kentucky/94 (American lineage). The canary pox infection of the host cell is abortive, with no virus produced, but influenza viral gene is expressed and presented through MHC class I by the host cell, with subsequent induction of an immune response. In preliminary reports it provides protection against infection by homologous virus, or by A/eq/Newmarket/05/03, the cause of the 2003 outbreak of influenza in Britain, 2 weeks after vaccination. The vaccine was used to aid in the control of the 2003 influenza outbreak in South Africa.

Other novel vaccine strategies include use of DNA or vector vaccines. Although effective in inducing a protective response, technological issues currently limit the widespread use of DNA vaccines.

Objective
The objective of a vaccination program is to ensure that horses have maximal immunity at the times of greatest risk of exposure to influenza virus. Therefore, young horses should be adequately vaccinated before being introduced into larger populations of horses. Older horses should receive frequent booster vaccinations before, and during, the racing or show season. Mares should be revaccinated before being shipped to breeding farms. It is important in any control program that all horses in a herd be vaccinated so that the population immunity to infection is maximal.

Timing
Foals
Timing of vaccination of foals depends on the immune status of the mare, and consequent acquisition of passive immunity by the foal. The presence of even small amounts of maternally derived antibody interferes with the immune response of foals to vaccination. Furthermore, vaccination of foals while they continue to have passive immunity can result in impaired responses to subsequent vaccinations. The practical significance of this latter observation is unknown but because of its potential importance should be considered when developing vaccination protocols for foals. Therefore, vaccination of foals born to mares vaccinated more than once yearly should be delayed until the foals are at least 24 weeks of age when the immunity resulting from the vaccination is much better; this might leave some foals unprotected because passively acquired immunity is shortlived and some foals of recently vaccinated dams are seronegative by 4 weeks of age. Foals of unvaccinated mares can be vaccinated at less than 1 month of age. Vaccinations are carried out at 6 to 12-week intervals for at least two injections. Subsequently, booster injections are given at least once a year, although more frequent vaccination confers a greater immunity.

Race and show horses
Yearlings and young horses are at increased risk of disease, and careful attention to their vaccination status is important in reducing the incidence of disease in this group. Yearlings and 2 year olds in racing stables in Great Britain typically have antibody concentrations against influenza prior to vaccination on arrival at the stable that are not protective. Vaccination increases antibody titer such that approximately three quarters of yearlings and 2 year olds have protective titers. For yearlings entering training the important predictors of antibody titer prior to vaccination on arrival at the stable were the time since a previous vaccination, total number of previous vaccinations, and the age at first vaccination. This study demonstrates the need for appropriate vaccination of young horses before they enter larger populations of horses, both to protect the young horse from disease and also to confer herd immunity on the population that they are entering.

Vaccination of race and show horses and other horses at increased risk of exposure should be frequent. Booster vaccines should be timed to maximize immunity at the time of greatest exposure, such as introduction to a new stable or at the beginning of the show season. For maximal protection subsequent booster injections should be administered at intervals of 6, or even 4, months. Measurement of antibody concentrations by single radial hemolysis can be useful in determining the need for booster vaccination. Previously, vaccination during the racing season was disliked by trainers because of transitory swellings at injection sites and an infrequent mild systemic reaction, however administration of contemporary vaccines is rarely associated with these adverse effects. In general, vaccination appears to have no adverse effect on performance.

Schedule
Various schedules have been proposed for influenza vaccinations of horses, with different regulatory bodies having specific recommendations. The FEI requires all horses competing in FEI competition to provide evidence of sufficient vaccination against equine influenza. This involves regular six monthly booster vaccinations following a primary vaccination course. All horses and ponies for which an FEI
Passport or a National Passport approved by the FEI has been issued must have the vaccination section completed and endorsed by a veterinarian, stating that it has received two injections for primary vaccination against equine influenza, given between 1 and 3 months apart. In addition, a booster vaccination must be administered within each succeeding 6 months (± 21 days) following the second vaccination of the primary course. None of these injections must have been given within the preceding 7 days including the day of the competition or of entry into the competition stables.

The UK Jockey Club has strict vaccination requirements which must be complied with to enter horses in their competitions or onto their premises. The program includes a 1st equine influenza vaccination to be followed by a 2nd vaccination 21 to 92 days later, with a 3rd vaccination 150 to 215 days from the 2nd vaccination. Thereafter vaccinations should be annually, with the last permissible day being the same date as the previous year’s vaccination. Horses may not race until the 8th day after the day of vaccination.

A schedule proposed for control of influenza in a large area includes the following rules:

- Mandatory vaccination for all horses entering racing premises.
- Horses not to race in the 10-day period following vaccination.
- Horses coming from international locations must be vaccinated before departure.
- All horse events, including shows, sales and gymkhanas, should apply the same restrictions.

The recommended vaccination program using inactivated or subunit vaccine is:

- Mares should be vaccinated during the final 4–6 weeks of gestation to ensure adequate passage of passive immunity to the foal.
- Vaccination of foals at 6 months of age.
- Two vaccinations initially at 21 days, and not more than 92 days apart.
- A booster vaccination 5–7 months later.
- Annual boosters or, in the face of increased infection pressure or when the risk of infection is high, boosters should be at 6-month or even 4-month intervals.
- When vaccination schedules break down and a horse goes longer than 12 months without a booster, recommence with a two-vaccination schedule.

Yearlings and 2-year-olds may require an additional vaccination between the second vaccination of the primary series and the booster at 6 months.

Control measures

Hygienic precautions can be of value in limiting the spread of the disease. Vehicles used for the transport of horses are thought to play a large part in transmission and should be thoroughly disinfected between shipments.

Quarantine is imperative to prevent introduction of virus by animals in the incubation period of the disease or subclinically infected horses. The most common introduction of infection, especially internationally, is through importation of subclinically infected horses. Also, because vaccinated animals can be infected and be shedding virus but not have signs of infection, isolation of introduced animals is an essential precaution, especially when an outbreak is in progress. The period of isolation should be at least 21 days. The degree of isolation required cannot be specified because of lack of basic information, but it is suggested that droplet infection can occur over a distance of 32 m and that maximum security with regard to clothing, utensils and personnel must be practised. Additional measures are a requirement for recent (4–8 weeks) vaccination, measurement of antibody concentrations in imported horses to ensure that they have protective immunity, and testing of imported horses on arrival for viral shedding. The later can be accomplished through use of rapid diagnostic tests (see above).

Control measures during an outbreak are intended to eliminate sources of infection, reduce transmission of virus, enhance the resistance of at-risk horses, and decrease the number of horses at risk. Infected horses (identified by stall-side or rapid laboratory tests) and clinically affected horses should be removed from the group and isolated for 3–4 weeks. Ventilation of shed rows and barns should be optimal to minimize aerosol spread of the virus. No horses should be introduced or allowed to leave until the outbreak is over, probably about 4 weeks after the first case is identified. Movement of horses between barns or paddocks should be avoided. Training and racing should be suspended. The opportunity for fomite transfer on clothing, tack, feed utensils or vehicles should be minimized by strict hygiene. Vaccination of clinically normal horses in the face of an outbreak can enhance the immunity of at-risk horses, and is probably safe.

REVIEW LITERATURE

EQUINE HENDRA VIRUS INFECTION (FORMERLY EQUINE MORBILLIVIRUS)

ETIOLOGY
An acute disease of horses transmissible to humans and characterized in horses by fever and respiratory distress occurs uncommonly in northeastern Australia. The disease is associated with the recently recognized equine Hendra virus (Henipavirus in the family Paramyxoviridae, formerly equine morbillivirus) which is closely related to Nipah virus and more distantly related to Menangle virus, both of which cause disease in pigs and humans.

EPIDEMIOLOGY
The disease in horses is uncommon, with four known occurrences between 1994 and 2004 affecting 23 horses with death of 17 horses and 2 humans. Serologic evidence of infection in horses is similarly rare — no seropositive horses were detected among 2000 horses examined on 166 properties. Similarly, no serologic evidence of infection was detected in samples from 500 pigs at 100 piggeries.

Transmission
The source of the virus is a wildlife host, the frugiverous pteropoid bats (fruitbats and flying foxes, Pteropus spp.). Bats are seropositive for antibodies to the virus, the only seropositive mammals of 34 wildlife species sampled, and the virus can be isolated from pteropoid postpartum uterine fluid and fetal tissue. The mechanism of spread from bats to horses is uncertain, but it is speculated that ingestion by horses of infected bat fetal fluids and tissues might transfer infection from bats to horses. Fruit bats were consistently present in all four occurrences of the disease which occurred during the fruit bat birthing season.

Dissemination of infection between horses by mechanical spread of infected nasal discharge likely occurred in the largest outbreak, and may have been the route of infection of the human fatalty. The virus is present in nasal discharges and urine of infected horses and spread from horse to horse might also occur through inhalation of infected urine. Mosquitoes do not appear to be important in the spread of infection. Human to human transmission of infection has not been reported.

Disease occurs in horses, humans, cats, and guinea pigs, though in the latter two species the disease was a result of experimental infection. Fruit bats do not develop clinical disease when experimentally infected.

Zoonotic potential
The disease has important zoonotic implications as two human deaths, one of encephalitis and the other of pneumonitis and respiratory failure, occurred in people who had close contact with clinically ill or dead horses. However, the virus does not appear to be easily transmitted to humans as most people in contact with clinically affected horses did not develop antibodies to the virus.

CLINICAL SIGNS
The incubation period of the spontaneous disease is 8–11 days, but is much shorter in experimentally-induced disease. Clinical signs of the disease in horses include depression, loss of appetite, fever, ataxia, tachycardia, tachypnea and copious frothy nasal discharge. Horses may show aimless pacing, hemorrhagic nasal discharge and swelling of the head. Death in acutely affected horses is associated with severe respiratory distress. Two of the four horses that survived the initial disease displayed localized myoclonic twitches involving the upper forelimb and the lower lip, face and upper hindlimb muscles. Clinically inapparent infections of horses occur.

CLINICAL PATHOLOGY
Characteristic changes in the hemogram or serum biochemical profile are not reported. If infected animals survive more than a few days after the onset of clinical signs they develop serum neutralizing antibodies. Antibodies are detectable by immunofluorescence or a rapid immune plaque assay. Viral genome can be detected by RT-PCR that is highly specific. Viral isolation in Vero cells or imaging using electron microscopy demonstrate presence of the virus. Details of diagnostic tests are available from the OIE.

NECROPSY
Necropsy examination reveals pulmonary edema with hemorrhage and froth in the airways. Histologic examination reveals an interstitial pneumonia characterized by extensive vascular damage as well as necrosis of alveolar macrophages. Pulmonary vascular changes include edema and hemorrhage within alveoli, plus necrosis and thrombosis of alveolar capillaries and small arterioles. The distinctive histologic feature is the presence of syncytial giant cells within blood vessels of the lungs and other organs. Although only a small number of cases have been examined, it appears unlike most other morbillivirus infections, intracytoplasmic or intranuclear inclusion bodies are not visible using conventional light microscopy. Retrospective diagnosis of the disease can be documented using an immunohistochemical technique or demonstration of viral nucleic acid in tissue by a test based on the PCR.

TREATMENT AND CONTROL
There is no specific treatment for this disease. The control measures in the described outbreaks included slaughter of all infected horses, extensive serological testing and control of movement of horses within a defined disease control zone. The disease in index cases is likely attributable to contact of susceptible horses with infected fluids of pteropoid bats and interventions that prevent or reduce the frequency of this occurrence are sensible, although the efficacy of this control technique has not been determined. A vaccine is not available.

CAPRINE HERPESVIRUS-1 INFECTION

Synopsis
Etiology Caprine herpesvirus-1
Epidemiology Most infections subclinical. High seroprevalence in Mediterranean countries. Latent infection common and outbreaks of abortion and neonatal mortality with no known precipitating cause
Clinical findings Abortion, neonatal disease, vulvovaginitis, balanoposthitis
Clinical pathology Leukopenia in systemic disease in kids
Lesions Ulceration and necrosis. Multifocal necrosis in intestine and organs. Aborted fetuses and young kids
Diagnostic confirmation Virus isolation, PCR
Treatment and control No effective treatment. Herd biosecurity. Experimental vaccine shows protection

ETIOLOGY
Caprine herpesvirus-1 (CpHV-1), an alphaherpesvirus within the family Herpesviridae. Restriction endonuclease
The disease is recorded in the United States, Canada, Australia, New Zealand, and some countries in Europe and probably has worldwide distribution. Within the countries where it occurs there is serological evidence that the infection is widespread. Seroprevalence is particularly high in Mediterranean countries with high goat populations.1-3

In adults, the systemic disease is clinically inapparent, but a genital form of the disease can be transmitted sexually. The virus causes latent or subclinical infections, such as vulvovaginitis and balanoposthitis, which may sometimes present as very serious forms. It is also associated with occasional but severe outbreaks of abortion where the abortion rate may approach 50%. CpHV-1 is also associated with severe systemic disease in 1-2-week-old kids.6,7 This may occur in herds where doings are also aborting or occasionally in herds without accompanying abortion.

Transmission and experimental reproduction
Transmission is thought to be by inhalation and ingestion because of the presence of the virus in nasal, pharyngeal and vaginal discharges and in the feces. The virus is excreted for 7 days after infection. The transmission rate is high, especially in the genital form. Only goats are affected, lambs and calves not succumbing after intranasal instillation although lambs may be infected by IV injection. After primary infection CpHV-1 establishes latent infection. Sites of latent infection sites have been identified as the third and fourth sacral ganglia but it is difficult to reactivate these infections either by experimental or natural means. Reactivation has been observed at the time of estrus and outbreaks of vulvovaginitis occur in the post mating period.2

However, the factors that precipitate the occasional outbreaks of abortion and disease in young kids are not known. Abortion has been reproduced by experimental challenge occurring 1-7 weeks after challenge. Challenge of females in early pregnancy is followed by fetal stunting and death but with challenge in mid pregnancy the there is no fetal growth impairment and the fetus carried to term but born dead.11

Economic importance
Causes of loss include deaths of young goats, in which the morbidity and case fatality rates are high, and abortion and stillbirths in ewes. Although the disease is not common abortion rates are high in herds that experience disease.

PATHOGENESIS
In 1-2-week-old unweaned kids a septicemia occurs, with infection developing in various organs, especially the alimentary and respiratory tract. With fetal infection the virus crosses the placenta and infects it, causing placentitis and invading the fetus.

CLINICAL SIGNS
Adults
In both the experimentally produced and the natural disease there is no prodromal clinical disease preceding abortion and aborted kids appear full term. Where there are twins one may be born dead and the other alive.5 In cases of genital disease there is vulvar erythema and edema, and shallow erosions and ulcers on the vulvar and vaginal mucosa. The vaginal discharge is clear to mucopurulent. The lesions heal in approximately a week’s time. Outbreaks occur in the post-mating period and are not necessarily followed by abortion. In males, there is hyperemia and ulceration of the penis and prepuce with a purulent exudate.

Newborn kids
Consistent signs include weakness, anorexia, cyanosis and dyspnea, increases in heart and respiratory rates, abdominal pain, fluid gut contents accompanied by diarrhea and dysentery, in some cases. Vesicles and ulcers may also be present on the coronets. Some show conjunctivitis, a seropurulent nasal discharge, erosions of the oral mucosa, and petechial hemorrhages in the skin.

CLINICAL PATHOLOGY
Leukopenia is a consistent finding in sick newborn kids. The virus can be isolated from all secretions and can be identified by PCR and restriction endonuclease analysis. In serum, antibodies can be demonstrated by a serum neutralization test, ELISA tests and radioimmunoassay.

DIFFERENTIAL DIAGNOSIS
The systemic disease needs to be differentiated from the severe mycoplasmal infections and bacterial septicaemias. Ulcerative dermatitis may be a confusing diagnosis in the genital form. Causes of abortion for differential diagnosis are in Table 18.8.

TREATMENT AND CONTROL
There is no treatment, although NSAIDs may ease the discomfort in the genitals caused by the disease. Quarantine and serological examination of all introduced goats seems the only effective control measure that can be adopted at the present time. An inactivated vaccine has been shown to engender protection,12 but the disease is probably not common enough that this would be commercially available.

SWINE INFLUENZA

SYNOPTIC

Etiology Influenza A virus subtypes H1N1, H1N2 and H3N2 of Orthomyxovirus

Epidemiology United States, England, Japan, Canada, Belgium, Young pigs. High morbidity, low mortality. During cold months. Antigenic diversity of virus. Aquatic birds natural reservoirs. Spread between pigs

Signs High incidence of anorexia, fever, thumps, muscle stiffness, recovery in several days

Clinical pathology PCR test to detect virus. Hemagglutination test and ELISA

Lesions Marked congestion of upper respiratory tract. Exudate in bronchi. Atresia. Suppurative bronchiolitis

Diagnostic confirmation Demonstrate virus in tissues

Differential diagnosis list
- Enzootic pneumonia
- Hog cholera
- Inclusion body rhinitis
- Atrophic rhinitis

Treatment Antimicrobials for secondary infection

Control No effective measures available. Vaccines are in use in certain parts of the world

INTRODUCTION

Swine influenza is an important cause of bronchointerstitial pneumonia throughout all pig keeping areas of the world. Real problems are associated with the changing viruses that cause disease.

ETIOLOGY

Classical swine influenza is associated with influenza A virus subtypes H1N1, H1N2 and H3N2 belonging to the Orthomyxovirus genus of the Orthomyxoviridae family. Other types have been isolated from pigs but as yet have not established as widespread endemic strains.

EPIDEMIOLOGY

The segmented nature of the viral genome is a critical structural feature that enables them to be reassorted. Since 1998, H, N and PB1 polymerase genes from human viruses, M, NS and NP genes from classical swine viruses and PA and PB2 polymerase genes from avian viruses have also been found.1,2

Occurrence There are three groups of viruses but only influenza A viruses are important in pigs. They occur in a large number of species including humans, primates, pigs, horses, sea mammals, and birds.3 When new variants occur in pig husbandry they are usually found in the pig population before they acquire the ability to spread rapidly and become associated with disease. They are named using the following convention: A/species/localization/isolate number/year of isolation, e.g. A/Wisconsin/125/98. If no species is indicated it is a human virus. They are described with reference to the hemagglutinin (H1 or H) and the neuraminidase (NA or N) that project from the surface of the viral envelope. There are 15H and 9N forms that can be distinguished antigenically and genetically and all of these have occurred in waterfowl and shore birds. They provide a permanent source of infection as does the water on which they float.4 The H binds to sialic acid and mediates the virus infection of the host. It also contains most of the antigenic sites. The N protein catalyses cleavage of sialic acid.

Swine influenza first appeared in the United States immediately following the 1918 pandemic of human influenza, and it was generally believed that it was caused by adaptation of the human influenza virus to swine. Nucleotide sequencing of the genes coding for the internal virus proteins indicates that the human pandemic H1N1 strain and the classic swine strain H1N1 have a common avian ancestor. It is suggested that a virulent avian strain H1N1 entered the human population in 1918 causing the pandemic. The pandemic virus was then introduced into the swine population where it has persisted unchanged. In contrast, swine influenza was seen in the UK in 1941 but then disappeared until it was seen in Czechoslovakia in 1950 and Germany in 1959. Influenza was not seen again until observed in swine in Europe in 1979 possibly following importation of pigs from North America, associated with a virus antigenically related to contemporary avian H1N1 strains found in ducks.5 These avian like strains have been the most common since 1979.6

Swine influenza still occurs in the United States and viruses of the H1N1 lineage were the dominant cause of SIV from 1930 to the 1990s.7 These were highly conserved (relatively unchanged) but new antigenic and genetic variants did occur.7,8 Classical H1N1 viruses have also been isolated from pigs from South America, Europe, and Asia. Wild pigs also have H1N1.8 In the 1980s there were many genetic mixings between avian-like H1N1 and human-like H3N2 viruses.9 In 1992, many outbreaks of classical swine influenza occurred in England, associated with a group of H1N1 viruses that were distinguishable from classical swine viruses, the European swine viruses, and human H1N1 viruses, all of which are known to be circulating in pigs.10 Influenza A virus subtypes H1N1 and H3N2 are endemic in pigs in Great Britain.11 Two distinct antigenic variants of H1N1 viruses have been associated with outbreaks of swine influenza, one of which was probably transmitted from birds to pigs in the early 1990s.5 The H1N2 subtypes isolated from pigs in Great Britain appear to have originated from a human H1N1 virus, which was circulating in the pig population in the 1980s, and from swine H3N2. It is suggested that the H1N1 viruses have disappeared from the human population, and the pig population provides a reservoir for the virus.11 Serological surveys indicate that a swine H1N1 influenza virus has circulated in the swine population in North America for many years.10 Recent isolates from Quebec possess a hemagglutinin distinguishable from subtype H1N1.12

Epidemics of swine influenza have also occurred in Japan, Canada, Belgium, and France. In North America, human H3N2 have been found much less often than in the rest of the world but the very recent introduction of H3N2 from humans to pigs was probably the major factor in the emergence of the recent strains.

Mixtures of human and classical virus genes have been isolated from pigs in Asia and the USA.13 H3N2 viruses with human H and N genes and avian internal protein genes have been isolated from pigs in Asia14 and H3N2 has been found in Korea14 and are currently the dominant H3N2 viruses in pigs in Europe.15 Since 1998 double and triple re-assortants have been isolated from pigs in the USA. The N. Carolina virus had three human genes and five swine genes,16 They include human H and N genes, genes from swine H1N1 viruses and two others from avians.17-19

Soon after the occurrence of the H3N2 viruses, new H1N2 viruses arose in the USA where the human H3 had been replaced by a porcine H120 and then spread.21,22 They had been known elsewhere in the world for some time: Japan23; France4; Germany24; Taiwan.25 They were described in the UK where they were found to be the most severe cause of pathology associated with the SIV viruses.22 These were all re-assortants between human H3N2 and classical H1N1.

Human H3N2 and avian H1N1 were isolated in the UK,6 and were then found to have spread to Europe.26-32 They are usually human H and N and the rest avian genes but one Italian virus has an avian H1.28 They have shown considerable genetic drift in Europe.33 Subtype H3N2 has been isolated in Canada from pigs with severe proliferative and necrotizing pneumonia (PNP),34 although this PNP is probably associated with PRRS and PCV2. Serological surveys indicate the infection is widespread in the swine populations in some countries.
The first unusual virus to be found in pigs was an H9N2 introduced to pigs in SE Asia probably from land-based poultry.35

Further problems occurred in the autumn of 1999 when an avian H4N6 was found in pigs with pneumonia on a commercial swine farm in Canada.36 Since then the avian H5N1 has appeared in pigs in China and is being carried west by bird migrations into Russia. The potential of avian viruses to spread to pigs and persist in pigs is unknown. Even if the viruses do not replicate they can contribute viral genes to other pig viruses. This is the reason for continual surveillance of SIV viruses. These were wholly avian viruses that were of North American lineage. It was the first report of an interspecies transmission of an avian H4 virus to domestic pigs under natural conditions.

The disease usually affects young pigs, but all ages may be affected. Typically, sudden onset epidemics occur with a high morbidity rate but with a low case fatality rate of less than 5%. Loss of body condition is marked, which is usually the important cause of financial loss, although occasionally death losses may be extensive if the pigs are kept under inadequate conditions or if secondary bacterial infections occur. Abortions and deaths of newborn pigs have also been reported as causes of loss in this disease.

Risk factors

Animal risk factors

Young, growing pigs are most susceptible. The viral infection is commonly complicated by bacterial infection due to Haemophilus parasuis, A. pleuropneumoniae, and possibly other opportunists of the upper respiratory tract of the pig. When an epidemic occurs, most of the pigs in the herd are affected within a few days, which suggests that all animals are previously infected and that some risk factor, such as inclement weather, precipitates the epidemic.

The agent also contributes to the Porcine Respiratory Disease Complex. In a recent study in Korea 14 of 105 cases had SIV,37 whereas in Iowa it has been reported in 19% of the cases of PRDC.38

Environmental risk factors

Epidemics occur mainly during the cold months of the year, commencing in the late autumn or early winter and terminating with a few outbreaks in early spring. Several days of inclement weather often precede an outbreak. Three risk factors for SIV were identified on a survey of Belgian finishing farms39 were H1N1 were found in 71% and H3N2 were found in 22%. There was a close association between H1N1 and H3N2. H1N1 appeared to be associated with fully slatted floors, increasing numbers of pigs in the locality and dry feeding. H3N2 was associated with the purchase of pigs from more than two herds, increasing numbers of pigs locally, and natural ventilation.

Pathogen factors

Molecular microbiology has now revealed the antigenic diversity of the virus. Several different H and N antigens have been identified and grouped on the basis of serological tests, which refine the diagnosis and reveal more about the epidemiological relationships. The H3N2 strain similar to H3N2 strains found in the human population has been isolated from an outbreak in England.53

Two antigenically distinct H1N1 influenza A viruses were isolated during an outbreak of respiratory disease in swine in Canada in 1990/91.40,41 One is a variant of the swine H1N1 influenza virus that is widespread in the American Midwest, whereas the other is similar to the virus isolated from swine in 1930. This suggests that influenza viruses can be maintained for long periods in swine herds, especially in certain geographical areas. It is proposed that the antigenic diversity of these viruses may be due to the result of drifts in the population of circulating swine influenza viruses in an area.7 The antigenic diversity oligonucleotide analysis of strains isolated from outbreaks in Sweden indicated a similarity with the Danish strain. One of the Swedish strains was closely related to the US strain.

The H1N1 strain of the virus can be found in pig tissues at slaughter but it does not persist for more than 2–3 weeks in deep frozen or refrigerated storage.

Methods of transmission

The natural reservoir of influenza A virus is aquatic birds. Various subtypes have been established in other species, such as influenza A H1N1 viruses, which infect human and different animal species. The influenza viruses may be transmissible between humans and pigs. Swine are the sole animals known to be susceptible to influenza A viruses of human, swine, and avian origin. Swine may become infected with related type A human influenza strains during epidemics of human influenza, but show no clinical signs of infection. The human strains have been isolated from pigs in Hong Kong, and pigs may serve as a reservoir for pandemic strains in humans as well as a source of genetic information for recombination between human and porcine strains. In Japan, pigs may be seropositive to human H3N2 viruses unassociated with human epidemics of disease.42 In Czechoslovakia, influenza A viruses are brought into pig herds by carrier people.

Pigs can be naturally infected with a range of avian influenza viruses. There have been at least three independent introductions of distinct wholly avian viruses into pigs.43,44 The virus in the late 1970s spread throughout Europe and the UK and became a major cause of St.45 These viruses also undergo drift.45,46

Elsewhere in the world antibodies against H4, H5, and H9 viruses have been isolated from Asian pigs47 and avian H4N6, H3N3 and H1N1 viruses have been recovered from pigs in Canada.

Swine are susceptible to both human and avian viruses because they have receptors on their respiratory epithelial cells for both avian (receptor SA α 2, 3 Gal) and human (receptor SA α 2, 6 Gal).48 Several re-assortants have been isolated from pigs in the USA and other parts of the world.49,50

Thus, swine have an important role in the ecology of influenza A viruses and are regarded as a ‘mixing vessel’ for the introduction of reassorted viruses into the human population.40,43,51

There is a report claiming that outbreaks of influenza in turkeys followed outbreaks of swine influenza in pigs from nearby swine herds.52 Swine and other influenza viruses have also been isolated from cattle, and experimental inoculation of calves has been successful. The swine influenza virus may cause natural infection in cattle and the virus can be transferred to un inoculated calves.

The primary route of infection is through pig to pig contact via the nasopharyngeal route. Peak shedding occurs 2–5 days post-infection (>107 infectious particles/mL at a peak).53,54

The rapid spread of infection from pig to pig occurs by inhalation of infective droplets. The disease may appear almost simultaneously in several herds within an area following the first cold period in late autumn. The virus can persist in infected swine, which can act as convalescent carriers and be the reservoir of the virus between epidemics. However, the experimental inoculation of a swine influenza virus into specific pathogen-free (SPF) pigs resulted in a mild disease and the period of viral shedding was shorter than 4 weeks.

Immunity

Both cell-mediated immunity and humoral responses are important. They do not prevent infection but they can mediate the killing of infected cells. The immune response is rapid and completes elimination
of the virus within 1 week. Antibodies decline by 8–10 weeks. The IgA levels in nasal washes are the most important defence. There is limited cross-protection between different viruses and protection after vaccination is more virus specific.

Maternal protection will last from 4–14 weeks with no pigs being completely protected from nasal virus shedding upon challenge but at least the lung is protected. Pigs with a high maternal antibody level did not develop an immune response. Maternal antibody does not cross protect between subtypes.

**Zoonotic Implications**

Swine influenzas pose a significant health risk to humans ever since the first human and porcine outbreaks in the USA in 1918. By 1970 there was evidence that people who came into contact with pigs through their jobs became infected with the viruses and a virus was isolated from pigs and stockmen. There is very little evidence of maintenance of human H1N1 in the pig populations but human H3N2 have been recovered regularly from pigs in Asia and Europe. The drift that has taken place in pigs of former human H3N2 has also been minimal compared to the rate of drift in the human population. The viruses from pigs found in humans have been reviewed.

**Pathogenesis**

Classical swine influenza was originally described as a disease of the upper respiratory tract, the trachea and bronchi being particularly affected, with secondary bacterial pneumonia due to Pasteurella multocida. However, recent descriptions of the lesions in naturally occurring cases and in the experimental disease indicate that the primary lesion is a viral interstitial pneumonia. Viral replication takes place in the epithelial cells of the nasal mucosa, tonsils, trachea, lungs and tracheobronchial lymph nodes. No other sites have been detected and viremia is of low titer. Inoculation of the H1N1 strain of influenza virus isolated in England from pigs with clinical disease into 6-week-old pigs caused fever, coughing, sneezing, and anorexia. A widespread interstitial pneumonia, with lesions in the bronchi and bronchioles, and hemorrhagic lymph nodes was characteristic. The H3N2 swine influenza virus isolated in Canada is associated with a proliferative and necrotizing pneumonia (PNP) of pigs, and there is evidence the strain may be related to A/Swit/Hong Kong/68H3N2 swine influenza virus. There is recent evidence that this PNP is more a feature of PRRS and PCV2 than SIV. A new antigenic variant of H1N1 swine influenza virus isolated in Quebec has been associated with proliferative and necrotizing pneumonia of pigs.

In the United Kingdom there has also been recorded an H1N7 which included both equine and human influenza genes. It was of low pathogenicity for pigs, found on only one farm, and did not establish in the pig world. Re-assortant H3N1 viruses from human and classical swine H1N1 have also been seen in the UK and also in Taiwan.

The virus causes an acute infection with shedding beginning on day 1 and finishing by day 7. Infected cells in the respiratory tract are reduced by 2–3 days post-inoculation. Most of the effects of the infection are caused by the production of proinflammatory cytokines (IFN-α, TNF-α, IL-1, and IL-6). These produce inflammation, fever, malaise, loss of appetite. The depth of infection in the lung probably determines how much of these cytokines are produced.

Contrary to widespread belief there is no evidence that the virus causes reproductive failure in swine. The experimental inoculation of seronegative pregnant gilts did not reveal any evidence of transplacental transmission of the virus to the fetus.

**Clinical Findings**

It is essentially a herd disease. The signs have not changed over the 80 years. After an incubation period of 1–7 days, (usually 1–3), the disease appears suddenly, with a high proportion of the herd showing fever (up to 41.5°C, 107°F), anorexia and severe prostration. The animal is disinclined to move or rise because of muscle stiffness and pain. Labored, jerky breathing (‘thumps’) is accompanied by sneezing and a deep, painful cough which often occurs in paroxysms. There is congestion of the conjunctivae with a watery ocular and nasal discharge. Sometimes there is open mouthed breathing and dyspnea especially if the pigs are forced to move. Morbidity is usually 100% but mortality is rarely above 1%. In general, the severity of the illness appears greater than, in fact, it is and after a course of 4–6 days signs disappear rapidly depending, in part, on the level of colostral antibody. However, there is much loss of weight, which is slowly regained. Convulsions are common in the terminal stages in fatal cases. The condition may continue to affect the herd for several weeks as the disease spreads, especially so if the herd is outdoors and the population dispersed. The new H3N2 re-assortants in the USA have been associated with respiratory disease but also spontaneous abortion in sows and death of adult pigs.

**Clinical Pathology**

Within 24 hours of the onset of clinical signs there is a switch of cells in the bronchial lavage from macrophages to over 50% neutrophils.

**Serological Tests**

After infection has ceased to circulate in the herd SIV AB could still be demonstrated after 28 months post-infection. It is extremely important to make sure that the antigens that are used in the serological tests are contemporary to the viral strains that may be found in the country.

Diagnosis of acute SIV infections requires the use of paired serum samples. The hemagglutination inhibition test has been the recommended test for many years and still remains so. However, it is tedious and has only moderate sensitivity but high specificity. It has been adapted and modified. One HI test for H1N1 will detect other H1N1 strains but this is not true for H3N2 when the Midwest strains are compared with the N. Carolina strains as they differ considerably. Above 1:80 is usually considered positive and within 5–7 days the titers may reach 1:320–1:640 by 2–3 weeks post-infection. An ELISA-based test is now available to estimate the hemagglutination titer and can be used at the herd screening level.

**Detection of Virus**

Virus is likely to be found in the nasopharyngeal area during the acute phase of the disease. Swabs should be taken on Dacron, placed in transport medium stored at 4°C for no more than 48 hours but if for longer freeze at −70°C. Viruses can also be isolated from trachea or lung tissues of pigs. They can be grown in hens’ eggs or increasingly in tissue culture. Samples need to be cool and moist. The virus is then detected by hemagglutinating activity in egg fluids about 5 days after inoculation. There are some strains that may not grow in hens’ eggs or require more than one cell line to isolate and identify the virus which may require 1–2 weeks.

**Antigen Detection**

A PCR test can be used to detect virus in nasal swab specimens and give results similar to virus isolation.
developed to detect H1 and H3 subtypes of SIV.\textsuperscript{85}

The virus can be detected by direct immunofluorescence of lung tissue or lavage fluids.

Immunohistochemistry on fixed tissue is also useful. The positivity is mainly in the bronchial and bronchiolar epithelial cells and less intense in the interstitial cells and alveolar macrophages.\textsuperscript{84}

**NECROPSY FINDINGS**

Swelling and marked edema of cervical and mediastinal lymph nodes are evident. There is congestion of the mucosae of the pharynx, larynx, trachea, and bronchi. A tenacious, colorless, frothy exudate is present in the air passages. Copious exudate in the bronchi is accompanied by collapse of the ventral parts of the lungs. This atelectasis is extensive and often irregularly distributed, although the apical and cardiac lobes are most affected, and the right lung more so than the left. It may reach 50% by 4–5 days post-infection.\textsuperscript{85,86} The affected tissue is clearly demarcated, dark red to purple and often reminiscent of enzootic pneumonia. Surrounding the atelectatic areas the lung is often emphysematous and may show many petechial hemorrhages.

Histologically, in acute swine influenza the major feature is necrotizing bronchiolitis.\textsuperscript{87} There is a suppurrative bronchiolitis and widespread interstitial pneumonia characterized by the early appearance of neutrophils followed by the accumulation of macrophages and mononuclear cells in the alveolar walls.\textsuperscript{64} After a few days there is a peribronchial and peribronchiolar infiltration of lymphocytes.\textsuperscript{87} In the variant of H1N1 swine influenza in Canada, there is more diffuse damage to the respiratory epithelium, resulting in firm to mealy lungs that appear thymus-like on cut surface.\textsuperscript{12}

Microscopically, there is marked proliferation of type II pneumocytes, in addition to the presence of macrophages and necrotic inflammatory cells in the alveoli. The influenza type A virus can be demonstrated by indirect immunofluorescence staining using monoclonal antibody directed to certain protein parts of the human type A influenza virus.\textsuperscript{13} The influenza type A virus can be detected and differentiated from the virus of porcine reproductive and respiratory syndrome in formalin-fixed, paraffin-embedded lung tissue using immunogold staining.\textsuperscript{89}

**Samples for confirmation of diagnosis**

- These are best collected from animals with high fevers and clear nasal discharge. Most pigs may excrete virus for 5−7 days post-infection but the peak load may be around 24 hours post-infection
- **Histology** — formalin-fixed lung, trachea, turbinate (LM, IHC). After 72 hours there is little IFA or IHC positivity. Histopathology may help in the diagnosis for 2 weeks post-infection
- **Virology** — nasopharyngeal swab in viral transport media; lung and trachea (ISO, FAT, PCR) fresh chilled but not frozen. Keep cool. Do not use cotton.

**DIFFERENTIAL DIAGNOSIS**

The explosive appearance of an upper respiratory syndrome, including conjunctivitis, sneezing, and coughing, with a low mortality rate, serves to differentiate swine influenza from the other common respiratory diseases of swine.

Enzootic pneumonia of pigs is most commonly confused with swine influenza, but it is more insidious in its onset and chronic in its course.

Hog cholera is manifested by less respiratory involvement and a high mortality rate.

Inclusion body rhinitis in piglets may resemble swine influenza quite closely. Atrophic rhinitis has a much longer course and is accompanied by characteristic distortion of the facial bones.

**TREATMENT**

No specific treatment is available. Treatment with penicillin, sulfadimidine, or preferably a broad-spectrum antibiotic may be of use in controlling possible secondary invaders. The provision of comfortable, well-bedded quarters, free from dust, is of major importance. Clean drinking water should be available, but feed should be limited during the first few days of convalescence. Medication of the feed or water supplies with a broad-spectrum antibiotic for several days is a rational approach to minimizing secondary bacterial pneumonia.

**CONTROL**

There are only two options vaccination and biosecurity. Biosecurity is difficult as experimental vaccines continue to be produced including a human adenovirus 5 recombinant expressing the hemagglutinin and nucleoprotein of H3N2 SIV has been used experimentally to provide protection against challenge with H3N2.\textsuperscript{94} Complete protection was shown by lack of nasal shedding and by lack of lung lesions following subsequent challenge.

**REFERENCES**

Inclusion body rhinitis, associated with a beta herpesvirus (family Herpesviridae), is an extremely common, but generally minor, disease in young pigs. It was first recognized in 1955. The virus is now called porcine herpesvirus 2. The disease has probable worldwide occurrence and has also been described in Canada and Japan and clinical and serological observations suggest that it is present in most pig herds. SPF herds established by hysterec-tomy techniques are not necessarily exempt and congenital transmission of the virus has been demonstrated. When the virus first enters a susceptible herd then both trans-placental and horizontal virus transmission takes place. Antibody responses start quickly so there are often no clinical signs but widespread infection.

The virus is present in the upper respiratory tract of pigs and the major infection site is the conchal (turbinate) epithelium. High excretion occurs predominantly in the 2–4-week period after infection. Transmission is via the respiratory route through direct contact and aerosol infection, and possibly also via urine. The virus invades epithelial cells, especially those of the nasal mucous glands, to produce destruction of acinar cells and metaplasia of the overlying epithelium and the major clinical manifestation is that of upper respiratory disease. Following infection, the virus may become generalized. In older pigs, generalization is restricted to epithelial cells of other organ systems, especially those of the renal tubules, and is clinically inapparent. However, in very young pigs the virus also shows a predilection for reticuloendothelial cells, and generalization may result in further clinical abnormality.

Clinically, the disease affects piglets up to approximately 10 weeks of age but the age at manifestation in any herd can depend upon the method of husbandry. In the UK, it is assumed that approximately 50% of the herds are infected. Within the individual herd there may be up to 98% affected. The disease usually occurs when the virus is introduced into the susceptible herd or if for some reason there is a huge increase in the number of susceptible pigs. A wide age-spectrum of involvement may be seen initially when the disease is introduced into the herd for the first time. In most herds the disease affects pigs in the late suckler and early weaner stage. It is at its most severe in pigs under two weeks of age. Sneezing is the most prominent sign and frequently occurs in paroxysms and following play fighting. There is a minor serous nasal discharge which rarely may be blood-stained, and also sometimes mucopurulent with a brown or black exudation around the eyes. There may be coughing. The clinical course varies approximately from 2–4 weeks. All pigs within the group are affected but there is usually no mortality.

The virus also crosses the placenta so it is possible for intra-uterine infection to produce fetal death, and running after birth as well as very early pneumonia, rhinitis and poor piglet weights at weaning.

Generalized cytomegalic inclusion body disease may occur in pigs exposed to intra-uterine infection and usually occurs as an outbreak involving several litters. The syndrome is characterized by sudden death and anemia. There is often a history of scouring within the group within the first week of life, and affected pigs show skin pallor and often superficially appear plump and well-developed due to edema, especially in the neck and forequarter regions. Death, resulting primarily from anemia, occurs during the 2nd–3rd week of life, and mortality within the group may approach 50%. Petechial hemorrhages have been a feature of the experimentally produced disease in gnotobiotic pigs but do not necessarily occur in field outbreaks. A moderate anemia producing a check to growth, but without significant mortality, may also be seen in recently weaned pigs experiencing the disease. Many survivors may be stunted.

More serious effects from generalized infection are seen when piglets are exposed to heavy infection at a very young age. It also occurs when there are new imports and when intercurrent disease and poor nutrition reduce resistance. This commonly occurs in large herds with high...
density continual throughout farrowing and weaning houses. In addition to upper respiratory disease, infection at this age may result in enteric disease, sudden death, anemia and wasting, with a marked unevenness of growth within the litter.

There may be complete blockage of the nasal passages. It is believed that the olfactory epithelium may be damaged so that there is no sense of smell and that piglets may not then eat and that is the reason so that so many die.

Inclusion body rhinitis is not a primary cause of atrophic rhinitis. However, it is probably contributory in lowering local resistance to infection and in predisposing to more severe infection with Bordetella bronchiseptica and other respiratory pathogens.

The diagnosis of inclusion body rhinitis is commonly made following the demonstration of typical intranuclear inclusion bodies in histological sections from electively slaughtered piglets. Large basophilic inclusion bodies are found in the mucous gland cells of the turbinate mucosa and may also be demonstrated in exfoliated cells obtained via nasal swabs from live pigs. Small intra-nuclear inclusion bodies are found in the reticulo-endothelial cells. These are best taken from several pigs at the height of clinical infection. Diagnosis by virus isolation is uncommon, as the virus has proved difficult to grow, but will establish in porcine lung macrophage cultures. Antibody to infection may be detected by indirect immunofluorescent techniques. An ELISA is also a sensitive reproducible and practical test. Recently, a PCR has been developed and this showed that 59% of pigs tested positive. However only 59% of PCR positive pigs had clinical signs and lesions consistent with inclusion body rhinitis.

There is no effective treatment and in most herds none is warranted. With severe rhinitis, antibiotics may temporarily reduce the severity of secondary bacterial infection. Control of severe disease rests with managemental procedures that avoid severe challenge to very young piglets. It is also possible to produce virus-free pigs from hysterectomy-derived pigs but it is necessary to monitor.

REFERENCEs

ENZOOTIC PNEUMONIA OF CALVES

Etiology Mycoplasma spp., parainfluenza-3 virus, bovine respiratory syncytial virus, and other viruses; secondary bacterial infection.

Epidemiology Housed dairy calves under 3–5 months; high morbidity low mortality; veal calves; beef calves crowded in calving grounds; poor colostral immunoglobulin status; inadequately ventilated calf barns; excessive infection pressure on newborn calf because of close proximity to adult cattle in barns; economically important.

Signs Mild to severe dyspnea, fever, loud breath sounds over cranioventral lungs (consolidation), coughing, high morbidity, low case fatality rate, secondary bacterial pneumonia with toxaemia.

Clinical pathology Isolate pathogens from nasal swabs, transtracheal aspirates. Serology for seroconversion to viruses.

Differential diagnosis:• Pneumonic pasteurellosis due to Pasteurella haemolytica• Haemophilus somnii pleuropneumonia• Aspiration pneumonia• Dyspnea of enzootic muscular dystrophy• Chronic cases may resemble congenital cardiac defects.

Treatment Antimicrobials to prevent and treat secondary bacterial pneumonia.

Control Insure adequate colostral intake. Good housing and ventilation. Prevent crowding in calf barns. Raise dairy calves separate from adult cattle or in calf hutchers.

ETIOLOGY
The cause is multifactorial, associated with various species of viruses, bacteria, mycoplasma, and environmental and host risk factors contributing to the pathogenesis, severity and nature of the pneumonia. Pathogens like mycoplasma and viruses may act as primary pathogens, and certain bacterial species may cause secondary complications.

Mycoplasma spp.
The mycoplasma are considered as primary pathogens and probably the most important and most common etiological agents of calf pneumonia. Mycoplasma bovis is a major cause of calf pneumonia. In addition, Ureaplasma diversum, Mycoplasma dispar, and M. bovis are isolated with a high frequency from the lungs of pneumonic calves. M. canis is being isolated with increased frequency. Acholoplasma laidlawii and M. arginini are also found but of dubious significance. M. bovis produces clinical pneumonia experimentally in calves and has been isolated from severe epidermis of pneumonia in calves imported into one country from others. The prevalence of nasal mycoplasmal flora in healthy cows and calves in the same herds is much lower.

Parainfluenza-3 paramyxovirus
The evidence for viruses as primary etiological agents is based on virus isolation, serological evidence of active infection, lesions of viral pneumonia, and experimental infection. The parainfluenza-3 (PI-3) virus has been isolated most commonly from affected calves and inoculation of the virus into colostrom-deprived calves results in a pneumonia that resembles the naturally occurring disease.

Bovine respiratory syncytial virus
Bovine respiratory syncytial virus (BRSV) causes pneumonia in both dairy and beef cattle of all ages, but primarily in dairy calves under 6 months of age. BRSV isolates belong to an antigenic grouping different from that of human respiratory syncytial virus (HRSV), and two distinct antigenic subgroups of BRSV exist.

Mixed viral and other pathogen infections
A survey of viral infections of the respiratory tract of calves over a 3-year period revealed that only BRSV, the PI-3 virus and bovine virus diarrhea virus (BVDV) were significantly associated with disease. Seroprevalence and clinical surveys of calves raised as herd replacements in dairy herds commonly reveals evidence of PI-3 virus and BRSV infections associated with respiratory disease. The rhinoviruses, adenoviruses, reoviruses, and enteroviruses were also isolated but in much lower frequency, and were considered not to be important. Chlamydia spp. have been associated with respiratory disease in calves and usually as part of a mixed infection with viruses and bacteria. Bovine coronavirus have been isolated from calves with respiratory disease but their significance is uncertain.

Bacteria
Mannheimia haemolytica and Past. multocida may also be recovered from the lungs of calves with pneumonia and may act synergistically with the Mycoplasma spp. to cause a more severe and fatal pneumonia. Several different bacterial species including Streptococcus spp., Staphylococci spp., Arcanobacterium pyogenes, Histophilus somni and Pasteurella spp. may also be recovered from pneumonic lungs.
Viral diseases characterized by respiratory signs

EPIDEMIOLOGY

Occurrence

Dairy calves

Enzootic pneumonia occurs most commonly in housed dairy calves from 2 weeks to 5 months of age when being raised as herd replacements. Pneumonia can be responsible for up to 30% of all deaths of calves in dairy herds from birth to 16 weeks of age, second to enteritis which can account for 44% of all deaths. Some farms report cases of pneumonia, while others have none.

Pneumonia can be the single largest cause of death in veal calf farms. The calves are purchased at about 10 days of age, assembled into large groups of 25-50 per group and fed a milk substitute diet for about 16 weeks and then sent to slaughter. The peak incidence of disease occurs about 5 weeks after arrival in the calf house during which time PI-3 and BRSV are recovered most often.

BRSV appears to have assumed major importance as a causative agent of herd epidemics of pneumonia in housed dairy calves.6-8 Weaned beef calves, and even adult cows. Serological surveys indicate that the prevalence of infection is high and varies from 60 to 80% of the cattle populations examined. Most mature cattle in some populations have seroconverted to the virus. However, the incidence of clinical respiratory disease associated with BRSV is much lower. Respiratory disease in weaned calf6-8 months of age in North America has also been attributed to BRSV and is characterized by a sudden onset, commonly after the cold weather begins in the fall of the year.6-7 Affected animals are commonly in good bodily condition and well-nourished. BRSV was the most commonly isolated viral agent in a series of 14 epidemics of pneumonia in housed dairy calves. The disease may be mild, moderate, or severe.

In dairy herds, clinical disease attributed to BRSV may appear initially in the youngest calves from 2 to 8 weeks of age in which the mortality will be highest, followed by disease in the mature lactating cows in which milk production will drop.

Beef calves

Enzootic pneumonia occurs in nursing beef calves and can account for significant reductions in weaning weight and a significant cause of economic loss due to disease in the neonatal period.10 In cow-calves herds in northwestern Quebec, one of the major causes of a low percentage of weaned calf crop was the occurrence of diarrhea and pneumonia in calves under 2 weeks of age.11 Pneumonia can also occur after beef calves have been housed.12 Morbidity and case fatality

Morbidity rate and case fatality rates vary depending on the quality of housing and management provided, and the kind and concentration of viruses and bacteria that predominate in the environment at any one time. The morbidity rate may reach 100%, and the case fatality rate is usually less than 5%. In dairy calves under 3 months of age, the morbidity rate and case fatality risk for pneumonia were 25.6% and 2.25, respectively.13 The cumulative risk incidence of respiratory disease in dairy heifers from birth to 8 weeks of age was 8.4%.14 In acute respiratory syncytial viral pneumonia of calves there may be an unexpected acute onset of respiratory disease in which 80-90% of calves are affected, with a case fatality rate that may reach 30% or higher.

On veal calf farms, pneumonia can be the largest single cause of death, with mortality rates up to 3.7% and culling rates at 5.1%. Peak death and cull losses occur during the 7th and 8th week of production.5

In Ontario Holstein dairy herds, 15% of calves were treated for pneumonia before the age of weaning.15 Treatment rates for pneumonia increased slightly until about the 6th week of life and then declined until weaning. Calves that had pneumonia during the first 3 months of life had an increased risk of mortality before they reached calving age.16 In Holstein herds in New York, the crude incidence rate for respiratory disease within 90 days of birth was 7.4%.17 In those same herds, dullness of calves and unspecified diagnosis within 90 days of birth increased the hazard rate of death after 90 days of age 4.3-fold above that for heifers without dullness within 90 days of birth.18 These data indicate pneumonia in dairy calves in the first 3 months of age can have an adverse effect on long-term survival and subsequent growth rate.19,20

Methods of transmission

Aerosol infection and direct contact are the methods of transmission and both are accentuated in crowded, inadequately ventilated conditions. The principal mode of transmission of M. dispar among calves reared in dairy farms is the airborne route up to several meters in distance.21 Newborn calves raised in individual pens may become infected within 5-15 days after an experimentally infected calf is placed in the calf house.21

M. bovis has been isolated from calves exhibiting severe fibrinonecrotic bronchopneumonia that were imported directly from continental Europe into Northern Ireland.2

Risk factors

Because most of the pathogens described under etiology can be found in the respiratory tract of normal calves, it has been generally accepted that environmental risk factors, such as ambient temperature, relative humidity, air quality, and population density, are necessary to precipitate the disease. In addition, several animal risk factors make calves susceptible to the pathogens in their environment. There are also pathogen risk factors that determine the disease outcome.

Animal risk factors

The onset of calf pneumonia occurs between 2 and 4 weeks of age when the concentration of serum IgG, IgM, and IgA in the nasal secretions are lowest.22 When the concentrations of serum IgG begin to increase at about 2-4 months of age, the incidence rate of new cases of pneumonia begins to decline. The spectrum of colostral antibodies present in home-raised calves will depend on the spectrum of infection in the adult cows. Most calves that recover from clinical enzootic pneumonia are resistant to further attacks of the disease associated with the same infectious agents. Herd immunity to one or more viruses develops, and severe outbreaks of disease usually occur following the introduction of animals that may be carriers of infectious agents to which the resident animals are non-immune. In commercial veal calf units where market-purchased calves are being introduced on a regular basis, there is commonly a succession of minor epidemics of enzootic pneumonia. The incidence is highest in the recently introduced calves and the disease will occur in a small percentage of resident calves.

In a study of range beef calves from birth to 45 days of age, respiratory disease accounted for a total mortality of 1% and was associated with twins, which may result in a less viable calf at birth that may be neglected and abandoned.23 The risk of respiratory disease was also higher for male calves. The recent advancement of calving dates of beef cattle herds in the cold areas of North America from April-June to January-March results in crowded conditions in calving yards, which creates the environmental conditions similar to those of housed dairy calves. This has increased the incidence risk for enzootic pneumonia in beef calves.

In herds infected with BRSV, newborn calves acquire colostral antibodies to BRSV, which declines to undetectable levels in an average of about 100 days with a range of 30-200 days.24 It appears that colostral immunity does not protect calves from experimental or naturally occurring clinical disease, but active
immunity from natural infection with or without evidence of clinical disease will protect the animals from clinical disease but not from reinfection upon later exposures to BRSV.

Environmental and management risk factors

Environmental risk factors, such as inadequate housing and ventilation are major contributors to the disease process. These include calving area, calf housing, spatial separation between calves, mixing calves of different age groups, and seasonal effects. Dairy herds that do not house calves in groups prior to weaning, or that house calves in groups of seven or fewer calves per group, are less likely to be affected with high mortality rate due to respiratory disease. The calving area and environment can affect calf health through stress and the degree of exposure to infectious agents. Inadequate ventilation, improper climate control, and poorly constructed facilities can induce stress in calves. Crowding results in close contact and promotes spread of infection, and also results in excess moisture which, in the presence of inadequate ventilation (movement of air) and supplemental heat, causes a high relative humidity and chilling of calves. Many calf barns are old, adapted barns which are occupied for several months without depopulation and disinfection. Monitoring 48 dairy herds over 1 year in the National Animal Health Monitoring System, revealed that mortality was lower in herds that used calf hutches compared to those that did not. In commercial veal units, the longer the disinfection and vacancy break, up to 6–7 days, the lower the incidence of disease in new calf crops entering the unit. Ventilation is commonly inadequate because of poor design of the building.

Rapid changes in weather, particularly during the winter months, are often followed by outbreaks of acute pneumonia because of inadequate ventilation. A common practice during cold weather is to close the air inlets and turn off the ventilating fans in an attempt to maintain the inside temperature at a comfortable level. This results in increased relative humidity, condensation of moisture on walls and on the calves, leading to wet conditions, and the reduced ventilation results in an increase in the concentration of droplet infection. Attempts to correlate meteorological data with the daily morbidity rate have not yet provided evidence for the hypothesis that climatic factors have an influence on incidence. This may be due to the difficulties associated with accurately monitoring meteorological data, and the lack of a direct relationship between the environment outside a calf barn and the microclimate of the calf inside the barn. The disease appears to be most common during the winter months when calves are housed continuously and when ventilation is commonly inadequate.

Humid weather results in a marked increase in the percentage of bacterial colony-forming particles of less than 4–7 μm in size. This provides the beginnings of a sound physical framework for the explanation of this and other, as yet empirical, relationships between the microenvironment in calf barns and the etiology and epidemiology of calf pneumonia.

The management risk factors that can influence the incidence rate and mortality of calves with pneumonia include:

- Colostrum feeding practices
- General feeding practices
- Quality of perinatal care provided by the personnel
- Age at weaning
- Use of prophylactic antimicrobials
- Health management of the dams

The feeding of a coccidiostat to preweaned calves may be associated with an increase in the risk of pneumonia because herds with a history of disease would be more likely to feed a coccidiostat.

Factors associated with mortality to 21 days of life in dairy heifers in the United States include:

- First colostrum-feeding method, timing and volume
- Time of separation from dam
- Calving ease
- Twin birth

Up to 31% of mortality is associated with ineffective colostrum feeding. The longer the calf is left with the dam after birth, the greater the mortality, presumably due to greater exposure of the calf to pathogens harbored by the dam. Difficult calving also may interfere with the optimum ingestion of colostrum and absorption of immunoglobulins.

A path model of individual-calf risk factors for calfhood morbidity and mortality in New York Holstein herds indicated that management appeared to affect, directly and indirectly, the risk of respiratory disease within 90 days of birth. Being born in loose housing is strongly related to development of clinical signs of calf diarrhea within 14 days of birth, which in turn increases the risk of respiratory disease within 90 days of birth.

Calves reared as herd replacements may be born inside and raised indoors until they are about 6 months of age and then turned out to pasture for the summer. In the case of veal calf-rearing units, the calves are kept and fed indoors under intensive conditions from a few days of age until they reach 150 kg body weight (BW) at 12 weeks of age. In the barley-beef units, the calves are fed indoors on an intensive basis from weaning until they reach market weight at 10–12 months of age. In all of these situations, young, growing calves are raised together under confined conditions, which promotes the spread of bovine respiratory disease associated with several viruses, Mycoplasma spp., and Pasteurella spp. Based on serological surveys, most calves raised in close confinement will have become infected by several viruses, including the PI-3 virus, adenoviruses, bovine respiratory syncytial virus, infectious bovine rhinotracheitis, and bovine viral diarrhea. If natural exposure to these viruses, Mycoplasma spp., and bacteria is so widespread and inevitable, it raises serious questions about the rationale for vaccination. In most cases the effects of the viruses and Mycoplasma spp. are minimal. The stress factors associated with inadequate ventilation, high relative humidity and chilling, and the secondary bacterial complications are responsible for the onset of clinical disease.

Pathogen risk factors

The infectious agents are ubiquitous in the respiratory secretions of the animals and in their environment, and more numerous in crowded poorly ventilated conditions. The spectrum of infectious agents that are present and acting in a calf population and the severity of clinical disease will vary between farms, between countries, and from season to season. It has been assumed that the older calves and mature animals in a herd are the source of infection for the young calves. This assumes major importance in control measures that are commonly designed to rear calves separate from older animals.

Mycoplasma dispar colonizes the respiratory tract of experimentally infected young calves for several months and can be isolated from nasal swabs and transtracheal samples throughout the period of colonization. M. dispar and Pasteurella multocida have been cultured from transtracheal aspirates of dairy calves with pneumonia under 3 months of age. In calves aged 1–5 months in calf-rearing farms that purchase calves from dairy farms, the prevalence and level of colonization of the respiratory tracts with Mycoplasma spp. can be more than 90% over a 2-year period. M. dispar, M. bovirhinis, and Acholeplasma laidlawii have all been isolated from such calves. A high degree of colonization with M. dispar among 1 to 2-month-old calves on these rearing farms indicates the ability of the pathogen to spread among the calves and colonize
the respiratory tract. *M. dispar* is able to spread very rapidly among groups of calves, and airborne transmission is considered to be an important mode of transmission in addition to direct contact. The infection rate in the calves at the farms of origin is small.

The number and types of *Mycoplasma* spp. that colonize the nose and trachea of calves are influenced by the age of calves and not by the environmental temperature or relative humidity. *Mycoplasma* spp. start to colonize the upper respiratory tract of calves within days after birth, and the peak isolation rate from their nasal cavities occurs at about 2–6 weeks of age, and from the trachea at 6–8 weeks of age. Over 92% of calves collected from farms and reared in a controlled environment can harbor *Mycoplasma* spp. in their noses when they are 2 weeks of age. The rate of recovery falls gradually thereafter.

**Parainfluenza-3 virus** is commonly subclinical in a group of calves, and clinical disease may not occur until other pathogens are present or when adverse environmental conditions precipitate clinical disease. Following natural infection of young calves, the PI-3 virus may persist for several weeks. However, the presence of PI-3 infection may predispose to respiratory disease by interfering with normal pulmonary clearance mechanisms and allowing secondary invasion by bacteria or mycoplasmas.

**Bovine respiratory syncytial virus.** Infection with BRSV may be subclinical, mildly clinical, or highly fatal. Raising calves in close proximity to older cattle may result in constant exposure to infectious agents to which the mature animals are immune. The disease may be endemic on particular farms in which almost every calf experiences clinical disease. Herd epidemics may occur following the introduction of a different virus, such as BRSV, or following a breakdown in the ventilation system. The disease occurs specifically in nursing beef calves from 1 to 4 months of age while on pasture.

**Mixed flora.** While a mixed flora of viruses, mycoplasma and bacteria can be isolated from the respiratory tract of calves with pneumonia, and the unpassaged respiratory material can cause disease similar to the naturally occurring disease, the inoculation of pure cultures of *M. dispar, M. bovis,* and *Ureaplasmia* spp., or pure cultures of BRSV or PI-3, into calves does not produce the severe clinical disease seen in the field. The failure of pure cultures of a pathogen to produce a severe pneumonia may be for one of three reasons:

- Combinations of organisms are required for disease
- Laboratory passage of the pathogens, necessary for purification causes their attenuation
- Material in the respiratory secretion other than the pathogens identified is required for disease, which may include agents that were not detected by routine culture techniques.

**Economic importance**

The economic losses associated with enzootic pneumonia may be considerable. One estimate reports that the disease accounts for 50% of all calf mortality and a reduction of 7.2% in liveweight gain. In commercial veal units, the presence of enzootic pneumonia may be associated with a prolonged time in the unit because of reduced daily liveweight gain.

The economic loss due to calfhood morbidity and mortality is well-recognized by the dairy industry. However, the long-term effects of morbidity from diseases such as enzootic pneumonia on health and performance may constitute an even greater economic loss to the herd. Calfhood diseases occurring in the first 3 months of life may have serious long-term consequences. Heifer calves that are treated for pneumonia during the first 3 months of life are 2.5 times more likely to die after 90 days of age than heifers that are not treated for pneumonia. Heifer calves without respiratory disease are twice as likely to calve, and calved for the first time 6 months earlier, when compared to calves with respiratory illness as calves. Some studies have found no significant independent association with calfhood disease status with first lactation milk production. However, the population selected did not include all heifers affected as calves; a heifer could have a suboptimal rate of growth or unthrifty appearance and would be removed from the herd before milk production was measured.

**PATHOGENESIS**

**Mycoplasma**

The endobronchial or intratracheal inoculation of gnotobiotic calves with *Mycoplasma* spp. does not usually result in significant clinical disease. However, 2 or 3 weeks following inoculation, there is microscopic evidence of pneumonia. The lesions produced by experimental inoculation of calves with *M. bovis,* *M. dispar* or *Ureaplasmia* spp. are characterized by peribronchiolar and perivascular "cuffing," catarrhal bronchiolitis, and atelectasis. Intranasal inoculation of *Ureaplasmia diversum* into SPF calves results in thick cuffs of round cells surrounding the bronchi, bronchioli and blood vessels, and a lobular catarrhal pneumonia. However, clinical signs of pneumonia are not observed. Inoculation of *M. canis* results in only a slight pathological change which disappears 9 days after infection. *M. dispar* produces an alveolitis without cuffing lesions. It is thought that the *Mycoplasma* spp. are synergistic with each other, viruses, and bacteria in producing the lesions of subclinical and clinical enzootic pneumonia.

*M. bovis* pneumonia in calves is characterized by coagulative necrosis and accumulation of catarrhal exudate in the airways resulting in a sudden onset of marked dyspnea, fever, and poor response to therapy. The coagulative necrosis does not cross the interlobular septa, which is in contrast to *Mann. haemolytica* which crosses the septa.

**Viruses**

The respiratory viruses can cause a viral interstitial pneumonia affecting the cranial lobes of the lung which may be subclinical, mildly clinical or severely and highly fatal.

**Parainfluenza-3**

Subclinical viral pneumonia associated with the PI-3 virus uncomplicated by secondary bacterial invasion is usually of minor importance. In subclinical PI-3 infection in calves, seroconversion will occur and at necropsy there are microscopic lesions consisting of bronchiolitis, bronchial and bronchiolar epithelial hyperplasia, alveolar epithelialization, and giant cell syncytial formation. In the mild form there are slight clinical signs such as coughing and polyneea. In the severe form of viral pneumonia, such as in respiratory syncytial viral infection, there is severe dyspnea, with mouth-breathing and an expiratory grunt, but a marked absence of toxemia compared with a bacterial pneumonia. Death can occur without secondary bacterial bronchopneumonia. Atelectasis and consolidation of the anterior lobes of the lungs are characteristic and account for the loud bronchial tones audible on auscultation over the anterior ventral aspect of thorax. The experimental intranasal inoculation of the PI-3 virus into colostrum-deprived calves results in a pneumonia that is grossly and histologically similar to the naturally occurring disease. Within 2–4 days following infection there is bronchiolitis and bronchitis and cellular exudate in the bronchiolar lumina. These lesions become more severe and are accompanied by alveolar cell thickening and hyperplasia. Beginning at about 14 days following infection, there is healing of the bronchiolar and alveolar lesions. The bronchiolar exudate becomes organized by fibroblasts, and mononuclear cells predominate in the alveolar exudate. Bronchiolitis obliterans is
BRSV can replicate and induce cytopathological changes in airway epithelial cells which include bronchial ciliated and mucous cells and bronchial ciliated and non-ciliated epithelial (Clara) cells. Syncytial epithelial cells may be observed in bronchi, bronchioles, alveoli, and in alveolar macrophages. However, syncytial cell formation is not unique to infection with BRSV since it may also occur in other viral infections of the lung. Whether or not BRSV can predispose to bacterial pneumonia is unknown, but the changes in lung tissue associated with the virus may affect lung clearance mechanisms and predispose to secondary bacterial infection and inflammation.

The pathogenesis of acute fatal pneumonia due to the BRSV is not well-understood. The characteristic lesions are exudative or necrotizing bronchiolitis, atelectasis, interstitial edema, and emphysema. Field observations have recorded that the acute fatal disease is commonly preceded by a mild respiratory disease several days previously, which suggests that hypersensitivity may be an important pathogenetic mechanism causing lung injury. The second stage may follow initial improvement or recovery from the first stage, and is associated with the onset of extreme respiratory distress. However, these observations have not yet been validated. The acute fatal disease attributed to BRSV has been reproduced experimentally in colostrum-fed, conventionally reared 1-month-old calves.

**CLINICAL FINDINGS**

Regardless of the identity of the causative pathogen, the clinical findings in almost all enzootic pneumonias of calves are similar. In the experimental viral pneumonia, a febrile reaction occurs on about the 5th day and is followed by the appearance of rhinitis, pneumonia, and mild diarrhea. The fever is only moderate (40–40.5°C, 104–105°F). A harsh, hacking cough, easily stimulated by pinching the trachea, is characteristic.

In naturally occurring cases, the clinical findings are similar, although the fever is usually higher. This may be due to bacterial invasion in the early stages. The nasal discharge is only moderate in amount and is mucopurulent. On auscultation of the thorax the major abnormalities can be detected over the ventral aspects of the apical and cardiac lobes. The breath sounds are loud and harsh and represent breath sounds transmitted through consolidated lung. The intensity of the heart sounds is increased because of shrinkage of lung tissue in the cardiac area. The usual course ranges from 4 to 7 days. Some peracute cases of uncomplicated viral pneumonia die within 1 day after the onset of signs. Infections with the PI-3 virus generally cause mild respiratory disease characterized by coughing, nasal discharge, slight fever, and recovery in a few days.

*M. bovis* pneumonia in young calves is characterized by the sudden onset of severe dyspnea, fever, and rapid deterioration in spite of therapy.

In BRSV pneumonia there may be a sudden onset of acute pneumonia in 80–90% of a group of calves. The clinical findings are characteristic of a severe viral pneumonia. Affected calves are usually mentally alert and there is only a mild fever. There is polyneurop and dyspnea which in a few days become worse with mouth-breathing and an expiratory grunt. Loud breath sounds, indicating consolidation, are audible over the anterior lobes of the lung. Squeaky, wheezing sounds due to the bronchiolitis are also commonly audible over the periphery of the consolidated areas. Loud, cracking sounds due to interstitial emphysema may also be audible over the dorsal aspects of the lungs. Death may occur in 2–4 days in spite of intensive therapy.

When secondary bacterial bronchopneumonia occurs, the fever, dyspnea, and toxemia are usually more severe. When secondary infection with *Pasteurella* spp. occurs, the temperature rises to 41–41.5°C (106–106°F), the area of lung affected is much increased, and loud harsh breath sounds due to edema are followed by crackles and a pleural friction rub. These cases usually respond rapidly to adequate treatment. When *Arcanobacterium pyogenes* is the secondary invader, consolidation is marked, there is a profound toxemia and loud breath sounds. In cases where *Fusobacterium necrophorum* is present, the clinical findings are similar and pulmonary abscesses are likely to develop. Necrotic lesions are often present in the mouth and pharynx in these cases and the pulmonary infection probably originates from here. With both of these latter infections there may be some response to antibiotic treatment, but there is a predisposition to relapse soon after treatment is terminated. Coughing, dyspnea, anorexia and emaciation continue, and the animal eventually has to be destroyed.

**CLINICAL PATHOLOGY**

**Isolation of pathogens**

Nasopharyngeal swabs, transtracheal aspirates, and lung lavage samples may be taken for isolation of viruses, mycoplasmas, and bacteria. Special laboratory media are required to isolate *Mycoplasma* spp. Determination of drug sensitivity to the bacteria may be valuable, particularly...
when a number of calves are involved in an outbreak. The isolation of BRSV from natural infections is difficult due to the labile nature of the virus. The immunofluorescent antibody test for antigen detection is one of the most rapid, reliable, and sensitive tests for BRSV from tracheal aspirates, nasal swabs, and lung samples.

**Serology**

Serological tests have been more extensively used for confirmation of suspected BRSV infections. The standard serological test is a virus-neutralization test using microtiter plates. Others include a modified indirect fluorescent antibody test, indirect hemagglutination, and an ELISA test, the latter of which is considered to be sensitive and specific and has the advantage of giving test results within several hours whereas the virus-neutralization test requires 5–6 days for completion. The complement fixation test is less specific and less sensitive than the ELISA test.

**NECROPSY FINDINGS**

In uncomplicated viral pneumonia, irrespective of the specific cause, there are areas of atelectasis and emphysema in the apical and cardiac lobes, with little macroscopic involvement of the diaphragmatic lobes. In the later stages, a dark red consolidation featuring a hobnail appearance of the pleural surface affects most of the ventral portions of the apical and cardiac lobes. The lesions are always bilateral. Histologically, there is a broncho-interstitial pneumonia. Acute inflammation of the nasal mucosa, particularly on the turbinates and ethmoid bones, is usually accompanied by a marked, mucopurulent exudation. In PI-3 infection, intra-alveolar plasmatic inclusion bodies are widespread in the lungs; and after experimental infection, are present on the 5th day, but have disappeared by the 7th day after infection.

In respiratory syncytial viral pneumonia there is severe interstitial pneumonia and interstitial emphysema. Histopathologically, there is severe bronchiolitis, alveolitis with multinucleated syncytia (which often contain eosinophilic intra-alveolar plasmatic inclusion bodies), and alveolar epithelial cell hyperplasia.

When bacterial or mycoplasmal invasion has occurred, the lesions vary with the agent present. Extensive heparization with mottled red and gray lobules, and considerable interlobular aggregations of serofibrinous fluid, often accompanied by a fibrinous pleuritis, is characteristic of *Past. multocida* infection. Extensive consolidation and suppuration occur with *A. pyogenes* and *F. necrophorum* infections. In the latter case there may be necrotic lesions in the mouth and upper respiratory tract.

Confirmation of this diagnosis at necropsy is somewhat awkward, as the population of pathogens responsible may change between the time of disease onset and the death of the calf. In severe outbreaks it may be necessary to euthanize animals early in the course of the disease, or to perform serological surveys for respiratory pathogens among surviving herdmates.

**Samples for confirmation of diagnosis**

- **Histology** – lung (several sections), trachea, turbinates (LM, IHC)
- **Virology** – lung (several sections), trachea (FAT, ISO)
- **Mycoplasmology** – lung (MCULT, FAT)
- **Bacteriology** – lung (CULT).

**DIFFERENTIAL DIAGNOSIS**

Clinically, the diagnosis of pneumonia is usually readily obvious, but the causative agents are usually not determined. Young calves raised indoors and affected with a cough, nasal discharge, and pneumonia are usually affected with enzootic pneumonia associated with the agents described under etiology. The common diseases of the respiratory tract of young calves which may resemble enzootic pneumonia include the following:

- **Bacterial pneumonia due to Mann. haemolytica, Klebsiella pneumoniae or H. somni** in young calves characterized by severe toxemia, fever, dyspnea, grunting, and a poor response to therapy
- **M. bovis** pneumonia is characterized by sudden onset of dyspnea, fever, depression, and poor response to therapy in a group of calves
- **Calf diphtheria** usually affects a single calf and is characterized by inspiratory dyspnea, stridor, toxemia, fever, and obvious lesions of the larynx
- **Lungworm pneumonia** occurs in young calves at pasture, and marked dyspnea, coughing, and a few deaths are characteristic. A fever is common in lungworm pneumonia and there are loud breath sounds over the ventral aspects of the lungs, and loud and moist crackles over the dorsal aspects
- **Acute myocardial dystrophy** in young calves, following turn out on pasture, is characterized by sudden onset of weakness, polyneea and dyspnea due to pulmonary edema and lesions of the diaphragm, tachycardia and arhythmia, and skeletal muscular weakness
- **Aspiration pneumonia** occurs occasionally in calves that have been force-fed colostrum or milk. There is a sudden onset of marked dyspnea, anxiety and distress, and death may occur within a few minutes. However, some calves survive and there is marked dyspnea with abdominal breathing, and loud breath sounds and crackles over the dorsal and ventral aspects of both lungs. Some calves will recover completely in a few days
- **BRSV interstitial pneumonia** in weaned beef calves must be differentiated from pneumatic parietoceleus. In BRSV pneumonia there is a sudden onset of marked dyspnea, fever, anxiety but not toxemia, mouth-breathing in advanced cases, loud breath sounds and wheezes over both lung fields especially over the ventral aspects, and subcutaneous emphysema. Several animals are usually involved. Affected animals fail to respond to treatment with antimicrobials and the case fatality rate is usually over 75%. There may be a history of mild respiratory disease in the affected group about 10 days previously. In parietoceleus, depression, toxemia, fever, loud breath sounds over the ventral aspects of the lungs, and a favorable response to treatment are characteristic
- **Chronic enzootic pneumonia** is characterized by bronchiectasis and pulmonary abscessation, causing unthriftiness and a poor response to therapy.

**TREATMENT**

**Antimicrobial therapy**

Uncomplicated enzootic pneumonia associated with mycoplasma or viruses is unlikely to respond to treatment, but antimicrobial therapy daily for 3 days is indicated because of the high probability of secondary bacterial pneumonia. Any of the antimicrobials used commonly for the treatment of acute undifferentiated bovine respiratory disease are effective. The short-acting or long-acting oxytetracyclines, the trimethoprim-potentiated sulphonamides, and florfenicol are efficacious and are recommended. Penicillin, tilmicosin, and ceftiofur are also effective for the treatment of secondary bacterial pneumonia. Danofloxacillin has excellent in vitro activity against several field isolates of *Mycoplasma* spp. from cattle, and has potential for the treatment of respiratory infections associated with *Mycoplasma* spp. Early treatment is necessary to avoid the development of incurable secondary complications, such as pulmonary abscesses, pleuritis, bronchiectasis, and supplicative pneumonia. In commercial veal calf units, the case fatality rate can be kept to a low level by early and adequate treatment. In some cases it may be sufficient to treat animals once only, but a proportion of cases are likely to relapse after an initial response. Such cases require repeated daily therapy for 3–5 days. If the number of relapses in an area or on a farm is excessive, all cases should receive multiple treatments.
M. bovis strains in Europe are becoming resistant to antibiotics traditionally used for mycoplasma infections in particular oxytetracyclines, florfenicol, tilmicosin, and spectinomycin. Only danofloxacin showed any antimycoplasmic activity. Spectinomycin had only partial therapeutic effect in calves experimentally infected with M. bovis. The fluoroquinolones are still effective but their use in animals in controversial. Valnemulin, a pleuromutilin antibiotic with high activity against mycoplasmas had some beneficial effect when added to the milk from four days of age for 3 weeks of one-month-old calves with respiratory disease from which M. bovis was isolated in about 80% of cases. Treated animals had less severe clinical disease but individual treatment was still necessary.

Adjunctive therapy
Bronchodilators and NSAIDs as adjunctive therapy for enzootic pneumonia in calves are used but their efficacy is questionable.

Correction of adverse environmental conditions
The clinical management of an outbreak of enzootic pneumonia in calves must include correction of adverse environmental conditions, which may have precipitated the disease.

CONTROL
Environmental and managerial
Control of the disease in housed calves is dependent on effective animal and environmental management. Overcrowding, drafty or inadequately ventilated housing, exposure to inclement weather, and sudden changes in environmental temperatures are major risk factors. Recently purchased calves should be isolated for several weeks before being introduced to the group.

Ideal environmental conditions
Control is especially difficult and expensive in countries where the calves are housed for several months during the winter months in northern climates. The most comfortable ambient temperature for young calves ranges from 13 to 21°C (55–70°F) with a relative humidity of 70%. To achieve these environmental conditions requires a suitable insulation of the housing, exposure to inclement weather, and adequate movement of air to remove aerosol particles that may be infectious. This requires an adequate air inlet and outlet system, adequate capacity fans, and supplemental heat during very cold periods. The installation of recirculating air filter units can lead to a substantial reduction in the concentration of airborne bacteria to which calves are exposed. Field studies in veal calf units indicate that mean aerial bacteria concentration in filtered barns can be reduced by 45%, the number of calves requiring treatment reduced by 19%, the number of repeat courses of treatment and the total antibiotic usage reduced by 29% and 35%, respectively. At slaughter, the average area of lung consolidation in calves from filtered barns can be reduced by 35%. In general, air filtration can result in a reduction in both the incidence and severity of clinical and subclinical pneumonia in calves and in improved weight gain.

In spite of ideal hygiene and management it may not be possible to prevent the development of new cases if the infection already exists in a herd, or if cattle from other herds are moved into the herd. At present, it is feasible only to be vigilant and treat new cases urgently and vigorously, because a strict hygiene program may not be feasible in the average commercial herd. If management is inadequate and the general resistance of the animals is low, losses due to calf pneumonia with significant bacterial or mycoplasmal invasion can be sufficient to make calf-rearing unprofitable.

Calf barns or hutches
Where economics permit, the ideal situation is to construct a calf barn completely removed from the main adult cow barn to minimize the spread of infection from adults that may be symptomless carriers. After the colostral feeding period, calves are removed from the calving barn and placed in individual pens in the calf barn. The raising of young calves outdoors in calf ‘hutches’ or ‘igloos’ is highly satisfactory and economical, even in countries where the outside temperatures go well below freezing. With adequate bedding, protection from the prevailing winds and adequate nutrition, calves will grow satisfactorily. Dairy herds that have had difficulty controlling enzootic pneumonia of calves have found this system to be an excellent alternative to the construction of a stand-alone, well-ventilated calf house. Nutritional deficiencies, usually of energy and protein, are common in young calves and often accentuate the severity of the pneumonia. Young calves should receive a balanced calf starter grain ration supplemented with essential vitamins and minerals, and good quality hay beginning by at least 3 weeks of age.

Vaccines and immunization
There is insufficient information available from field trials to make recommendations for the use of vaccines for the control of enzootic pneumonia in calves. It is difficult to evaluate the results of vaccination trials because investigators use so many combinations of vaccines, different vaccination schedules, and there are many different management variables and differences in methods of evaluation. In addition, most vaccination trials are not randomized controlled trials.

Any successful vaccine would have to be multivalent and would have to be effective when given before 2 months of age or earlier to coincide with the decline in immunity and the occurrence of enzootic pneumonia in calves. A study of vaccination of calves in a commercial calf-rearing unit that compared the use of no Vaccine, intranasal infectious bovine rhinotracheitis (IBR), intranasal IBR–PI-3, and intranasal IBR–PI-3 plus BRSV on three occasions at 7, 10, and 16 weeks did not have a significant effect on growth rates during a 10-month period to slaughter. There is good field evidence that the collostral immunological status of the calf has a significant effect on the susceptibility of the calf to pneumonia. There is a clear association between low levels of IgG1, IgG2 and IgA of calves at 2–3 weeks of age, and subsequent susceptibility to pneumonia at 2–3 months of age. Calves with signs of pneumonia had low levels of IgG1 compared with non-pneumonic calves which had relatively higher levels. In addition, calves with high levels of serum immunoglobulin do not respond normally to vaccine and any vaccine for enzootic pneumonia would have to be administered during this relatively refractory period. However, for veal calves, which are purchased at a few days of age and with low levels of immunoglobulin, this may not be a problem.

The intranasal inoculation of calves with virulent or a modified strain of PI-3 virus stimulates the development of both serum antibody and nasal secretion antibody. The nasal secretion antibody is dose-dependent. Challenge exposure of these calves provides protection against clinical disease. These factors should be considered in the development and administration of PI-3 viral vaccines if the objective is to establish an optimal concentration of antibody in the nasal secretion. The parenteral administration of two sequential doses, 2 weeks apart, of a nonactivated PI-3 virus vaccine with adjuvant will induce high levels of serum antibody and prevent virus excretion in nasopharyngeal secretions after challenge. Successful immunization of calves against PI-3 infection may be useful for protection against pneumonic pasteurellosis if PI-3 precedes the bacterial infection. This is presented in greater detail in the section on pneumonic pasteurellosis.
A quadrivalent vaccine containing the inactivated antigens of BRSV, PI-3, M. dispar, and M. bovis, or a vaccine containing only BRSV, given to two vaccinated groups respectively, and compared to controls, provided protection against naturally occurring pneumonia and non-fatal respiratory disease in a large beef-rearing unit over a period of 2 years in the United Kingdom. Calves were collected from farms in the first few weeks of life and reared in the unit in groups of 100 until slaughter at about 18 months. The proportion of calves receiving treatment for respiratory disease was 38% in the control group, 25% in those vaccinated with the quadrivalent vaccine and 27% in those vaccinated with the BRSV vaccine. Mortality in the control group was 9%, 2% in the quadrivalent vaccine group, and 3% in the BRSV-vaccinated group. A single dose of an experimental vaccine for M. bovis pneumonia, inactivated with saponin, given subcutaneously to 3 to 4-week-old calves followed by experimental challenge 3 weeks later with a virulent strain of M. bovis provided protection against clinical pneumonia. Unvaccinated calves developed clinical signs of disease due to lung lesions. The vaccine also reduced the spread of M. bovis to internal organs. Calves tested 6 months after immunization had high levels of maternal antibody. The successful use of saponin in vaccines has been demonstrated for other mycoplasma infections such as contagious caprine pleuropneumonia (CCPP) and contagious agalactia. The saponin may preserve the major antigens and maintain an efficient immune response. The evaluations of BRSV vaccines are currently in progress and the preliminary results are inconclusive. A combined vaccine containing Mann. haemolytica, H. somni, and a modified live-virus for the control of enzootic pneumonia in young beef calves vaccinated at 3 and 5 weeks of age reduced the number of calves requiring treatment.

**ETIOLOGY**

The bovine respiratory syncytial virus (BRSV) is a cause of a viral pneumonia primarily in cattle under 6 months of age, and also yearlings and adult cattle. The BRSV is a pneumovirus in the family Paramyxoviridae. Isolates of the virus from calves with severe respiratory disease in a region of Britain are more closely related by genetic analysis sequences to US isolates than to earlier British and mainland European isolates. Importation of live cattle from North America to Britain may explain the relatedness of the isolates. The literature of the history and taxonomy of the virus has been reviewed.

**EPIDEMIOLOGY**

**Occurrence**

Prevalence of infection

The virus is ubiquitous in the cattle population and new infections occur most commonly in autumn and winter annually and may result in severe respiratory disease. In longitudinal studies in dairy herds, 90% of primary infections occur in calves and heifers; very few occur in cattle over 2 years of age, and all cattle in the herds are seropositive when they are over 3 years of age. Recurrent infections occurring annually at the same time, and in cows of all ages, without new introductions into the herd, are characteristic of BRSV infections in a herd. There is evidence that the virus circulates during spring or summer at very low levels or not at all. Persistent BRSV infection in some of the cows in a herd might be a means for the virus to survive during the summer, but a steady state of reinfection of seropositive cows throughout the year at a low level might also maintain a reservoir of infection. Monthly data on the prevalence of BRSV antibodies in dairy herds suggest that persistent infection in seropositive cows is more likely than population persistence.

While the prevalence of infection in the cattle population is high, the incidence rate of clinical disease is much lower in adult cattle than in young stock. An understanding of the sources of virus under natural conditions is essential to an understanding of the infection of young animals. Infections under natural conditions are characterized by the presence of persistently infected individuals, although the importance of these in the spread of virus remains unknown. It is postulated that virus may be spread via infected asymptomatic carriers and that infection may be spread via infected asymptomatic carriers and that infection may be spread via infected asymptomatic carriers.
lower. It can be assumed that most mature cattle have been exposed to the virus. Surveys in the United States, England, Denmark, Sweden, and France found seropositive rates in herds ranging from 50 to 80%. Cattle entering feedlots may seroconvert to the virus, which may be associated with an increased risk to subsequent treatment for respiratory disease. A high percentage of young beef bulls aged about 6 months and entering performance test stations may seroconvert to BRSV and adenovirus, both of which may be associated with clinical respiratory disease.

Occurrence of clinical disease
In general, calves under 6 months of age are most commonly affected and some BRSV infections are undoubtedly associated with enzootic pneumonia of housed dairy calves. In dairy herds, recent introductions of young cattle purchased from public saleyards may introduce the infection to home-farm cattle that have had no previous exposure to the viruses, or in which their immunity to a previous infection with the virus has declined. Thus, adult dairy cows may be affected with a highly fatal pneumonia due to the virus. A high prevalence of infection exists in Swedish cattle and annual outbreaks of disease have occurred in adult cattle, pregnant or recently calved cows being most severely affected. Outbreaks have occurred in beef cattle on pasture. The disease occurs in nursing beef calves 1-8 months of age on pasture with their dams without any history of previous stress. A common occurrence is in weaned beef calves 6-8 months of age within 2-3 weeks following weaning and commingling in confinement. Yearling cattle in feedlots are also susceptible.

In North America, herd epidemics of clinical disease usually occur during the fall and winter months. However, nursing beef calves may be affected with clinical disease during the summer months. Some outbreaks have occurred in nursing beef calves between 1 and 2 months of age while they are still in nursery pastures or in the calving areas. A spontaneous outbreak of respiratory disease in goats due to the BRSV has been described, and sheep can be infected with the virus. An epidemic of acute respiratory disease associated with the BRSV occurred during the winter and spring of 1995 in Norway. Data from 431 cattle herds were collected. The risk of acute respiratory disease occurring in cattle was related to herd size and type of production and an expressed interaction between these two variables. The risk of a herd outbreak in a mixed herd of 20 animals was estimated to be 1.7 times greater than in a dairy herd, and 3.3 times greater than in a beef herd of comparable size. On increasing herd size to 50 animals, the risk increased 1.3 fold for a mixed herd, 3.3 fold for a dairy herd, and 2.1 fold for a beef herd, compared to a risk for a corresponding type of herd of 20 animals. The disease spread initially from one location to another during the first 6 to 9 weeks, where the rate of transmission between neighboring farms seemed to be higher than for the other districts included in the study. It was hypothesized that one common source of infection was involved in the outbreak and the case herds were clustered in time as well as spatially. The average daily milk loss was estimated to be 0.70 kg per cow for 7 days after a herd outbreak compared with the period one week before.

Morbidity and case fatality
The morbidity rate in herd epidemics of clinical disease can vary from 30 to 50% or higher. The case fatality rate is usually low, 3-5%, but may be higher.

Methods of transmission
The mode of transmission has not been defined but aerosol infection and direct contact are probable. Infection spreads rapidly among susceptible cattle.

Risk factors
Animal risk factors
Naturally occurring BRSV infection affects both dairy and beef cattle and those under 6-10 months of age are most susceptible to clinical disease. Nursing beef calves with colostral BRSV antibody are not protected from infection but the incidence and severity of clinical disease is inversely related to the level of maternal antibodies in calves younger than 3 months. The highest percentage of reinfections occurs most commonly in cows during their first lactation. Older animals may have a more effective immunity because of previous exposure. Seroepidemiological surveys in feedlot cattle found that seroconversion to the virus may occur in up to 70% of animals within 1 month after arrival. Animals with low titers to the virus on arrival are at increased risk of subsequent treatment for respiratory disease, which suggests that the virus may be a factor in bovine respiratory disease. In some situations in feedlot cattle, high BRSV serum antibody levels on arrival were related to a lower risk of respiratory disease.

Environmental risk factors
The highest incidence of clinical disease occurs in autumn and winter months. Outbreaks have been associated with changes in weather, especially declining ambient temperatures and atmospheric pressure.

Pathogen risk factors
BRSV has a narrow host range, affecting primarily cattle. Important antigenic differences between BRSV isolates have been described. Subgroups A and AB are associated with severe respiratory disease and circulate in the Dutch cattle population. In natural outbreaks of infection in closed dairy cattle herds and veal calf units in Denmark, using DNA sequence data, identical viruses were isolated within a herd during outbreaks, but viruses from recurrent infections varied by up to 11% even in closed herds. It is possible that a quasispecies variant swarm of BRSV persisted in some of the calves in each herd and that a new and different highly fit virus type (master and consensus sequence) became dominant and spread from a single animal in connection with each outbreak.

Antigenic subtypes may have relevance both in explaining differences in virulence between subtypes and in the development of new vaccines for the control of clinical disease. The production and characterization of monoclonal antibodies to a vaccine strain of BRSV has been described. The respiratory syncytial virus of goats and sheep, caprine respiratory syncytial virus and ovine respiratory syncytial viruses are antigenically related, but not identical, to BRSV.

The BRSV may act synergistically with a concurrent experimental challenge of the virus and 3-methylindole to produce more severe pulmonary disease similar to BRSV pneumonia seen in feedlot cattle, than either agent alone. But vaccination of cattle with BRSV vaccines does not protect the potential synergism between the 3-MI and BRSV infection.

Whether or not the virus persists in individual animals in spite of the presence of maternal or naturally-acquired antibodies has been a major question. Serological findings indicate persistence of the virus but the virus could not be detected in lung lavage fluid or nasal swabs. Experimentally, the virus persisted in tracheobronchial and mediastinal lymph nodes for up to 71 days after infection. In vitro, the virus was still able to replicate in bovine B-lymphocyte cell lines 6 months after infection. This may explain the absence of the virus between epidemics, recurrent infections in the same individuals and inapparent re-infection of adults.

Immune mechanisms
After a natural BRSV infection, the protection is short-lived and multiple reinfections are common. In endemic
areas, the absence of BRSV-associated disease in adult cattle is possibly due to repeated infections. This places a constraint on vaccine development, because one or two vaccinations would have to induce immunity that only repeated natural infections can provide. BRSV infections can occur in the presence of high to moderate levels of maternal antibodies. Maternal antibodies, which are directed against the F, G and N proteins of BRSV, are commonly present in calves, but do not protect against infection. However, the incidence and severity are inversely related to the level of specific maternal antibody, and natural infection does not prevent reinfection but appears to offer good protection against clinical disease after infection.

The BRSV colostral antibody of dairy calves varies dependent on season of the year the calves are born. Dairy calves born during the winter months in the Netherlands have lower BRSV colostral antibody titers than those born during the summer months. This may be due to the seasonal periodicity of BRSV circulation or by other factors influencing antibody development or colostrum intake is uncertain. Calves born in the summer have higher antibody titers at 14 to 19 weeks of age most likely attributable to BRSV exposure. Calves born during the season of infection may be primed with BRSV field virus during the period of maternally derived immunity and may be better protected against disease by cellular immunity during the next season of infection.

IgM and IgA are the predominant antibody isotypes in the respiratory tract after BRSV infection, with IgA especially prominent after reinfection. Both serum antibody responses and local antibody responses are suppressed by maternal antibodies. After natural BRSV infection of cattle, antibodies are predominantly directed against the epitope A, whereas after experimental infection, or vaccination with an inactivated virus, the antibody responds against epitope B and non-neutralizing epitope C are markedly increased compared with the same epitopes in naturally infected cattle.

The subgroups of the virus are based on antigenic differences of the G protein, and BRSV infection protects against reinfection by homologous strains of the virus. It is also known that a complete BRSV can partially protect against a BRSV infection with a strain that contains an antigenic dissimilar G protein. Therefore, incorporation of representative viruses of different BRSV subgroups in vaccines for cattle does not seem necessary to achieve cross-protection. A G1-negative bovine herpesvirus-1 (BH-V-1) strain can successfully be used as a vector for development of combination vaccines against bovine respiratory disease, and the G protein can induce significant protection against BRSV infection in calves.

Vaccination of calves with a formalin-inactivated BRSV vaccine followed by challenge exposure to virulent virus increased the severity of clinical disease and lesions compared to calves non-vaccinated and challenged. Vaccination did not induce neutralizing antibodies, but IgG antibodies were detected with ELISA. Immunization with formalin-inactivated BRSV vaccine mainly primes a Th2-like inflammatory response characterized by a significant eosinophilic influx in the bronchio alveolar lung field and lung tissues and high levels of immunoglobulin E serum antibodies.

**PATHOGENESIS**

BRSV causes rhinitis, tracheitis, bronchitis, bronchiolitis, and mild interstitial pneumonia. In naturally occurring cases, the principal lesions are bronchitis and bronchiolitis in the cranioventral portions of the lungs combined with widespread emphysema and edema throughout the lungs. BRSV infection causes airway obstruction and hyperactivity that may persist for up to 30 days following viral exposure. In naturally occurring cases, the cranioventral lung fields are particularly poorly ventilated and there is arterial hypoxemia associated with mismatching of ventilation and perfusion. Radiographic and radionuclide lung perfusion imaging reveals the presence of bullous emphysema and areas of marked atelectasis.

The pathogenesis of acute fatal pneumonia due to BRSV is not clear. The characteristic lesions are exudative or necrotizing bronchiolitis, atelectasis, interstitial edema, and emphysema. The acute fatal disease is commonly preceded by a mild respiratory disease several days previously, which suggests that hypersensitivity may be a pathogenetic mechanism causing lung injury. The second stage may follow initial improvement or recovery from the first stage and is associated with the onset of extreme respiratory distress. The virus-specific IgE antibody may play a role in the pathogenesis of the severe disease as part of a hypersensitivity reaction. The IgM and IgA antibodies are not involved in a hypersensitivity reaction. In experimentally induced infection in calves, there is considerable injury to bronchiolar epithelium including hypertrophy, hyperplasia, and formation of syncytia. In the alveoli, BRSV infection results in necrosis of type I pneumocytes, the response of type II pneumocytes includes hypertrophy, hyperplasia, and syncytial formation. It is suggested that an immune-mediated mechanism may be responsible for the widespread lesions over the entire lung.

The severe highly fatal form of the disease, also known as the 'malignant' form, or the paroxysmal respiratory distress syndrome (PRDS) is associated with extensive pulmonary mast cell degranulation. In a series of naturally-occurring paroxysmal respiratory disease in calves, paired serum samples were taken three weeks apart, and lungs examined at necropsy. The serum concentration of tryptase was used as a marker of mast cell degranulation. Tryptase is a preformed serine protease stored in mast cell granules and causes significant changes in the respiratory tract smooth muscle tone and vascular permeability. The substances released by the mast cells are at least partially responsible for the pulmonary edema, in particular by means of vasoconstriction and the increase in the vascular permeability induced by the histamine. (In neonatal calves and young adult cattle, histamine affects respiratory function by contraction of the trachea and pulmonary veins which increases total pulmonary resistance and induce venous hypertension. This would likely result in increased pulmonary capillary pressure and the development of alveolar edema. The main physiopathologic target of pulmonary mast cells in cattle is the pulmonary vein.)

The edema and bronchoconstriction caused by the mast cell leukotrienes impeed bronchial flow, which causes ventilatory asynchrony. The mechanical constraints caused by the asynchrony are aggravated because the bovine lungs consist of a number of compartments, which prevents any collateral ventilation and any dissipation of interlobar pressure gradients. The breaking point is reached when the level of the mechanical constraints exceeds the level of tissue resistance causing interstitial emphysema.

Calves which die from the BRSV-associated PRDS have a uniform pattern of gross lesions. The trachea and bronchi are filled with a white-to-pink froth and the lungs are heavy and voluminous and fail to collapse. The most characteristic lesions were the dramatic lung distension by edema, alveolar hyperinflation and severe interstitial and subpleural emphysema, often with large dissecting bullae on the dorsal edge of the diaphragmatic lobes.

Microscopically, the most characteristic lesions are bronchitis, bronchiolitis, and alveolar edema, mononuclear cell infiltration, hyaline membrane deposition
and scattered hyperplasia of type-2 pneumocytes. There is a clear gradient in the severity of inflammatory changes in the airway along a cranio-caudal axis, lesions being more frequent and severe in the cranial parts except for hyperinflation and emphysema. Extensive mast cell degranulation occurs in the diaphragmatic lobes where neither the virus nor the epithelial syncytia, nor the bronchiolitis, typically observed in cranio-ventral zones are found.

Experimental reproduction of BRSV pneumonia

Experimental reproduction of the disease has been difficult; in most cases, infection results in only mild clinical disease with limited lesions.

Severe respiratory tract disease and lesions can be reproduced experimentally in conventionally reared calves and the virus can be recovered from tissues.24 Severe disease similar to the naturally-occurring disease can be induced with a single aerosol of a low-passage clinical isolate of the virus.24 Moderate to severe BRSV-induced pneumonia can be reproduced in colostrum-fed calves, and nasal shedding of the virus and demonstration of the antigen in the lungs at necropsy provides evidence that the virus causes the disease.27

In neonatal calves with experimental acute infection with BRSV, there is increased pulmonary resistance and decreased compliance, which explains the severe dyspnea observed in some calves. There is no evidence that transplacental infection occurs.3 Experimental infection of young lambs with BRSV can result in severe pathological changes with only mild clinical disease.29

In experimentally infected calves, the virus can be detected in the bronchiolar epithelial cells and in alveolar cells, including bronchial ciliated and mucous cells, and bronchiolar ciliated and non-ciliated epithelial (Clara) cells. Syncytia are often observed in the bronchiolar walls and in the alveoli, and such syncytia were always replicating the virus.29 However, syncytial cell formation is not unique to infection with BRSV since it may also occur in other viral infections of the lung.

Ultrastructural studies of experimental BRSV pneumonia reveal that ciliated and non-ciliated bronchiolar epithelial cells and alveolar type II pneumocytes are targets of the virus.3,3 BRSV infection of ciliated cells in the airway can result in the loss of cilia and ciliated cells, which may interfere with lung clearance mechanisms and predispose to bacterial pneumonia. The experimental inoculation of lambs with both BRSV and Mannheimia haemolytica results in a more severe acute respiratory disease than that produced by either agent alone, and the severity of the disease may be a result of synergistic action of the two agents.

Experimental BRSV infection in calves, induces an acute phase protein response.28 Strong and reproducible acute phase proteins haptoglobin and serum amyloid A will peak at 7–8 days after inoculation of the virus. The pro-inflammatory cytokine, tumor necrosis factor (TNF-α), can be detected in the broncho alveolar lung lavage fluids and high levels appear on the days when severe lung lesions and clinical signs are obvious.30 It may be involved in mechanisms leading to increased permeability of endothelium.

**CLINICAL FINDINGS**

The clinical findings vary considerably from herd to herd and from year to year. In dairy cattle, disease occurs most commonly in young calves under 6–10 months of age, although outbreaks of severe disease in mature dairy cattle also occur. Clinical signs of infection in older cattle, particularly those with previous exposure to the virus, are less severe. In large dairy herds, episodes of infection are usually mild and often unnoticed, despite cattle having a fever, slight inappetence, and a corresponding decrease in daily milk production which lasts 3–5 days.31 Primary infections in lactating dairy cattle may cause a considerable decrease in daily milk production. However, reinfections are not associated with an important loss of milk production. A sudden outbreak of acute respiratory disease in a group of animals is a characteristic of a primary BRSV infection. The disease is more severe in animals with no previous exposure to the virus. A dry, non-productive cough, severe dyspnea and polynpea, and bilateral nasal discharge are characteristic. A fever of 40–42°C (104–108°F) is common and milk production in lactating cows declines markedly. Feed consumption in the affected group declines for a few days. The fever usually persists for 3–5 days in spite of therapy with antimicrobials. Toxemia is not a feature unless there is secondary bacterial pneumonia. On auscultation of the lungs there are loud breath sounds over the ventral aspects indicating consolidation, and wheezes indicating bronchiolitis. These are the findings of a viral interstitial pneumonia. Most animals recover within 5–7 days. About 1–2% of affected animals will develop a fatal viral pneumonia characterized by severe dyspnea with abdominal breathing and an expiratory grunt, mouth-breathing with foamy salivation, marked anxiety, persistent fever, and death within 2–5 days after onset.33 Feed and water consumption are decreased because of severe dyspnea, which results in a gaunt abdomen and dehydration. Affected animals are reluctant to move or lie down. The loud breath sounds audible over the ventral two-thirds of both lung fields, indicating that extensive consolidation is becoming pronounced. Subcutaneous emphysema over the withers may also occur. Occasionally, some animals that are not being observed closely will die with peracute pneumonia within a few days and represent the index case of an outbreak.

In outbreaks of BRSV infection in young dairy cattle under 12–16 months of age, the first clinical abnormalities usually noticed by the owner are coughing and a mild nasal discharge in 50–75% of the animals. Inappetence with a fever of 40°C (104°F) or higher lasts for about 3 days followed by recovery in most cases. Coughing, nasal discharge, and conjunctivitis may persist for several days or a few weeks in 10–30% of the animals with no long-lasting complications. Abdominal breathing, and loud and abnormal lung sounds may occur in about 50% of the animals but these commonly resolve within 10 days.

In an outbreak of BRSV in recently weaned beef calves 6–8 months of age, nasal and lacrimal discharge, polyneea and dyspnea, fever of 40–42°C (104–108°F) decreased feed intake, coughing, and lethargy are common. In a small percentage of affected animals, within a few days the dyspnea becomes marked with mouth-breathing and the production of frothy saliva created by the labored respirations. Subcutaneous emphysema over the withers due to severe, interstitial emphysema also occurs. Loud breath sounds, wheezing, and crackling sounds are audible over the ventral aspects of the lungs. Death may occur within a few days after the onset of the dyspnea. Secondary bacterial broncho-pneumonia may occur but is uncommon.

**CLINICAL PATHOLOGY**

It is difficult to obtain a definitive etiological diagnosis of BRSV infection because the virus is highly labile in tissue samples and virus detection in specimens is poor because of inadequate laboratory techniques. The virus replicates slowly, classical viral isolation is laborious and several blind passages are often necessary before any cytopathic effect can be seen. Nasopharyngeal swabs for virus isolation and paired serum samples are necessary to make a definitive etiological diagnosis. Successful laboratory diagnosis of BRSV is generally based on one of four criteria:

- Virus isolation
- Detection of BRSV antigen in suspected tissues
Viral diseases characterized by respiratory signs

The high prevalence of antibody titers to the virus, and the need for skilled personnel to process and interpret the diagnostic tests, have hindered development of a routine diagnostic test. Successful isolation of the virus from typical clinical cases of disease is often unsuccessful and can take 11–21 days because of the late appearance of any noticeable cytopathic effect. Because of these difficulties, isolation of the virus is not commonly recommended as a routine diagnostic approach.

**Virus isolation or detection**

The ideal sample for isolation of the virus is a transtracheal aspirate in the very early stages of the disease. The sample also provides cells for **immunofluorescent antibody** (IFA) staining.

Nasopharyngeal swabs are also useful, but sampling technique must ensure good contact with the most caudal part of the pharyngeal cavity and the samples must be placed in viral transport medium and shipped on cold packs and not frozen.

The fluorescent antibody test for virus detection is one of the most rapid, reliable, and sensitive tests for the diagnosis of BRSV infection.

For tracheal aspirates, an aliquot of the sample is centrifuged onto a microscopic slide to obtain a cell preparation for the IFA test.

The **PCR assay** is rapid and sensitive and can be recommended as the method of choice in the analysis of clinical specimens.

The presence of the virus can be determined by using PCR on nasal swabs taken in the acute phase of a suspected outbreak. The virus can be detected and quantified in cell cultures using real-time quantitative RT-PCR and quantitative competitive RT-PCR assays.

A sensitive RT-PCR assay for detection of the virus in lung tissues from calves with natural or experimental infection has been developed.

The virus can be detected in tissues with monoclonal or polyclonal antibodies and avidin–biotin complex immunohistochemistry. This is typically done on formalin-fixed, paraffin-embedded tissues.

**Serology**

The standard serological test for specific BRSV antibodies is the **virus-neutralization** (VN) test, usually done with microtiter plates. Paired acute and convalescent samples from both affected and normal animals in the herd are desirable.

The indirect ELISA is a rapid and reliable test for detecting antibodies to BRSV in milk, bulk tank milk, and serum. A microneutralization ELISA has been developed which correlates well with other assays and is useful in assessing antibody responses to the virus both in naturally occurring disease and in vaccination studies.

A leukopenia and neutropenia are common and are aids to diagnosis.

**NECROPSY FINDINGS**

Affected lungs are voluminous and heavy, and fail to collapse when the thoracic cavity is opened. The cranioventral portions of the lung are consolidated and usually dark red or plum-colored. The interlobular septa are edematous, and mucoid exudate can often be expressed from small bronchi. Severe interstitial emphysema and edema are prominent over the dorsal and caudal lobes.

The interlobular septa of the caudal lobes are usually distended because of interstitial emphysema, and large bullae are common. The interlobular septa of the caudal lobes are usually distended because of emphysema and edema. Subcutaneous emphysema over the withers, thorax, and neck are common. Secondary bacterial broncho-pneumonia with pleuritis may occur.

Histologically, there is bronchiolitis and bronchitis. Large multinucleated syncytia are present, projecting from the bronchiolar walls or lying free in the lumen. Hyperplasia or necrosis of the bronchiolar epithelium are common. Exudates consisting of neutrophils, macrophages, desquamated epithelial cells, and syncytia are present in the bronchiolar lumina. Small airways are often occluded with exudate. Alveolar changes include cellular infiltration and thickening of alveolar septae with multinucleate giant-cell syncytia in the alveoli. Epithelial syncytia containing eosinophilic intracytoplasmic inclusion bodies are often present on alveolar walls.

The presence of epithelial syncytia is a useful feature but the numbers and prominence of these structures can vary considerably. Other viruses can also induce these syncytia. In the caudodorsal lung regions, there is severe emphysema, often with rupture of alveolar walls, alveolar edema, sometimes with hyaline membrane formation and swelling of alveolar epithelial cells.

In experimental BRSV pneumonia, the findings include bronchitis, bronchiolitis, proliferative and necrotizing bronchiolitis, interstitial pneumonia with areas of atelectasis and alveolar edema, epithelial syncytium formation on bronchiolar and alveolar walls, and pneumocyte hyperplasia.

The virus antigen can be demonstrated by immunoperoxidase or immunofluorescent staining of bronchiolar and alveolar epithelium.

Isolation of the BRSV from natural field cases has always been difficult because of the long duration required for the appearance of characteristic cytopathic effects. Fluorescent microscopy can be used for detection of the antigen in the cranioventral lung areas but PCR is a more sensitive technique. It is advisable to collect and sample several areas of lung as viral antigen/nucleic acid will be most abundant in areas of acute infection. The virus can also be demonstrated in formalin-fixed paraffin-embedded bovine lung tissue using immunohistochemical techniques.

**Samples for confirmation of diagnosis**

- **Histology** – fixed lung (several sites) (LM, IHC)
- **Virology** – chilled lung (several sites) (FAT, PCR); nasal swab (ELISA, PCR).

**Differential diagnosis**

The differential diagnosis includes those infectious diseases of the respiratory tract of young cattle that commonly affect groups of animals in a short period of time.

It is not usually possible to make a definitive etiological diagnosis based on the clinical findings. However, the combination of the epidemiological and clinical findings is usually suggestive of an acute viral respiratory disease. It is not usually possible to be more specific than making a clinical diagnosis of acute undifferentiated respiratory disease.

- **Acute respiratory disease due to BRSV infection in weaned beef calves** is characterized by marked dyspnea, anorexia, mouth-breathing, fever, subcutaneous emphysema, loud breath sounds, and death in a small percentage of animals in a few days or less. In some cases there may be a history of respiratory disease in the affected group several days previously.

- **Infectious bovine rhinotracheitis (IBR)** is characterized by outbreak of coughing, profuse nasal discharge, fever, inappetence, the presence of typical nasal lesions; pneumonia is not common. Recovery occurs in several days.

- **Pneumonic pasteurellosis** is characterized by anoxemia, toxemia, fever, abnormal lung sounds, coughing, nasal discharge, and response to treatment with antimicrobials: fibrinous pneumonia at necropsy is typical.

- **lungworm pneumonia** occurs most commonly in groups of young cattle on summer pasture and is characterized by coughing, nasal discharge, tachypnea, abdominal breathing, fever and inappetence, and increased breath sounds with crackles. A necropsy diagnosis is usually necessary.

- **BRSV infection in mature dairy cattle** may be mild and is characterized by a slight drop in milk production, fever for a few days, inappetence, and recovery in a few days. Adult cattle lacking immunity may develop severe fatal pneumonia which must be distinguished from pneumonic pasteurellosis, infectious bovine rhinotracheitis, and other cases of interstitial pneumonia.
TREATMENT

Antimicrobial therapy

Broad-spectrum antimicrobials given daily for 3–5 days for secondary bacterial pneumonia are commonly administered but may not be necessary. Recovery usually occurs gradually over a period of 3–5 days. Severely affected animals will become worse in spite of therapy.

Non-steroidal anti-inflammatory agents

These are used for their anti-inflammatory effect but are unnecessary and there is no evidence that they are efficacious.

CONTROL

Reliable control measures are unavailable. The ubiquitous nature of the virus, the persistency of infection in herds, the movement of cattle between herds, the expansion of herds and the replacement practices used in herds, and recurrent infections make control difficult.

Management

A rationale approach to control would be management of the herd to minimize stressors such as inadequate ventilation. Herd replacements brought into the herd should be quarantined from the rest of the herd for 2–3 weeks before mixing with the remainder of the herd.

Vaccines and immunization

Several modified live virus and inactivated virus vaccines are available for the control of respiratory disease due to BRSV infection, but there are few randomized clinical trials evaluating the efficacy of the vaccine under naturally occurring conditions against BRSV infection or clinical disease. Because calves under 6 months of age are most frequently infected with BRSV despite the presence of colostral antibodies, there is a need for a vaccine which is effective in calves. The presence of passively derived antibodies to BRSV interferes with immunization by vaccination of young calves with commercially available inactivated vaccines. Vaccines must therefore be effective at an early age and be able to overcome the immunosuppressive effects of colostral antibodies.

Protection has been reported in experimental challenge models in cattle for several vaccines: field trials, with live or inactivated BRSV vaccines revealed different levels of protection, while others found that vaccination enhanced disease in calves. The intramuscular administration of the vaccine in calves which had colostral antibodies, was least efficacious, and intranasal inoculation of live virus in colostrum deprived calves proved most effective.

Cattle vaccinated with MLV BRSV vaccines generally develop high concentrations of virus neutralizing antibodies (VN) and fusion inhibiting antibodies, compared with low to moderate concentrations of total BRSV-specific IgG. In contrast, cattle receiving inactivated virus vaccines develop lowered concentrations of VN antibodies and high concentrations of virus-specific (non-neutralizing) IgG.

Formalin-inactivated BRSV vaccines have not been successful when tested by experimental challenge of vaccinated calves. This is similar to the enhanced disease which may occur in children vaccinated with a formalin-inactivated alum adjuvanted vaccine. However, one adjuvanted inactivated BRSV vaccine did provide protection in vaccinated calves challenged by experimental infection.

A BRSV vaccine inactivated with beta-propiolactone and adjuvanted provided calves with colostral antibodies to the virus with protection against challenge with the virus. A study of three vaccinations in calves with high levels of antibodies or two vaccinations in calves with moderate levels provided protection for nearly 6 months. However, in one study in beef herds, calves vaccinated with an inactivated BRSV vaccine developed clinical, serological, virological and pathological evidence of BRSV pneumonia 2 months after vaccination.

A modified-live BRSV vaccine provided protection in calves against a challenge model that mimics severe naturally occurring disease. Vaccinated calves shed reduced numbers of virus, had less pulmonary disease, and had vaccine-induced cell-mediated immune responses. The cell-mediated immunity was a more consistent measure of protection than prechallenge serum antibody.

A single intranasal dose of MLV BRSV vaccine protected calves from experimental challenge and the vaccine induced cell-mediated immunity characterized by the production of BRSV-specific interferon-gamma (IFN-γ) by mononuclear cells isolated from various tissue specimens.

Subunit vaccines which can overcome maternal antibodies have been examined. The use of immunostimulating complexes (ISCOMs) against BRSV has been evaluated and compared to a commercial inactivated vaccine in calves with BRSV-specific maternal antibodies. Following experimental challenge, vaccinated calves remained healthy, while control calves developed severe clinical disease. Significantly higher BRSV-specific nasal IgG, serum IgG1, and IgG2 titers were detected before and after challenge in calves vaccinated with ISCOMs compared to the results in calves vaccinated with the commercial vaccine. BRSV was isolated from the nasopharynx of control calves none from the calves vaccinated with ISCOMs. The vaccine overcame the suppressive effect of colostral antibodies and induced a strong clinical and virological protection against a BRSV challenge.

Vaccination of dairy heifers with a vaccine containing chemically altered temperature-sensitive infectious bovine rhinotracheitis (IBR), PL-3 viruses, two strains of killed bovine virus diarrhea viruses, and a modified live virus BRSV, compared to a similar vaccine but without the BRSV, twice at a 2-week interval with the second vaccine administered at 2–3 weeks before calving, may increase milk production and first insemination conception rates. Milk production was increased in first-parity cows during the first 21 weeks of lactation. Vaccination did not have any effect on milk production after the first 21 weeks of lactation in cows of any parity.

REVIEW LITERATURE

REFERENCES

The literature on the evolution of the herpesviruses has been reviewed. Four ruminant alphaherpesviruses are related to BHV-1 and have the potential for cross-infection of cattle in Europe: Bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herpesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1.2 BHV-5 is the cause of fatal meningoencephalitis in calves.3 CpHV-1 causes enteritis and generalized infection in neonatal kids. Most CpHV-1 infections in adults are subclinical, the virus can cause vulvovaginitis, balanoposthitis, or abortion. CvHV-1 can cause ocular disease in red deer and is widespread in free-living and farmed red deer. CvHV-2 has been isolated from reindeer in Finland and serological evidence of infection with a virus similar to BHV-1 has been reported in caribou in Canada. Although these viruses differ considerably in their virulence, they are closely related both genetically and antigenically, and can establish latent infections similar to that of BHV-1.4 An immunofluorescence assay using monoclonal antibodies can discriminate between these related herpesviruses.5 Restriction endonuclease and monoclonal antibody analysis has been used to analyze Brazilian isolates of BHV-1 and BHV-5.6

Bovine herpesvirus 4 has been associated with mastitis in cattle.7,8

**EPIDEMIOLOGY**

Prevalence of infection and occurrence of disease

Disease complexes associated with this virus have been recognized in most cattle-raising countries of Europe, Asia, North America, Africa, and in Australia and New Zealand. The respiratory form of clinical disease is most common in feedlot cattle, and cattle on dairy and beef farms without a routine vaccination program. Seroprevalence surveys have found that 10–50%, or even higher, of cattle are serologically positive to the virus depending on vaccination practices in individual herds, and the frequency of contact between infected and non-infected animals.3 The percentage can also vary between dairy and beef cattle in the same geographical area. The seroprevalence in a country or area also changes over time. A serological survey in Belgium found that infection is endemic in the cattle population.9 In Great Britain in the 1960s, serological surveys indicated that less than 10% of cattle were positive. In the mid- to late-1970s, the incidence of infection increased markedly, and by 1986 35% of the animals and 48% of the herds were positive. In beef herds in northern Australia, up to 96% of bulls and 52% of cows are seropositive, most of which may become viremic because respiratory disease is uncommon in cattle on extensive range conditions. The genital carrier state is important in the maintenance of viremic IBR virus and in the occurrence of sporadic infectious pustular vulvovaginitis (IPV) and infectious pustular balanoposthitis (IBP) in these herds. Outbreaks of IPV and IBP were not uncommon in Britain in the 1960s and 1970s, and then occurred only rarely after the introduction of stricter control measures in artificial insemination units.10 In 1997, an outbreak of IPV and IBP occurred in a dairy herd with 70–80% of the cows manifesting signs of both the respiratory and genital form of BHV infection.10 Both ocular and nasal isolates were typed as type 2b, which is the same as the Oxford isolate commonly associated with both IPV/IBP and typical lowmedium virulence outbreaks of IBR.11

The bovine herpesvirus-1 has not been reported in recent years in a number of countries such as Norway, Sweden, Finland, Ireland, Iceland, Denmark, Bulgaria, and Moldova.12 Since 1994, Norway has been free of BHV-1 and certain defined additional guarantees for cattle to be imported are in place to protect the disease status.13 IBR/IBV is a reportable disease in Norway. Some countries in Europe are in the process of eradicating the virus from the cattle population. In beef herds in Yucutan, Mexico, where vaccination is not practised, seropositivity was associated with large and older herds.13

**Wildlife**

Bovine herpesvirus infections exist in wild ruminants.14 Infections may be endemic in white-tailed deer in certain parts of Canada, and it is suggested a mild form of the disease occurs in these animals. About 29% of both wild and farmed red deer in Britain are seropositive to the closely related herpesvirus of Cervidae 1. Mule deer are susceptible to infection, the disease has occurred naturally in a goat, and antibodies to the virus have been found in pronghorn antelope in western Canada, and in Tanzania in game animals and cattle. According on serological surveys, the virus is widespread in African wildlife, particularly the buffalo, which may be a reservoir of infection among the wildlife population. The virus has been recovered from the wildebeest in Africa, which suggests further that wildlife may serve as reservoirs. Antibodies to the alpha-herpesviruses were found in reindeer (28.5%), roe deer (3.0%), and in red deer (0.5%) in Norway.15 In Saskatchewan, Canada, 52% of Woodland...
Morbidity and case fatality

The uncomplicated form of the respiratory disease in cattle is not highly fatal. Most losses being due mainly to secondary bacterial bronchopneumonia. The morbidity and case fatality rates in dairy cattle are about 8% and 3%, respectively, while in feedlot cattle the morbidity rate is usually 20–30% in unvaccinated cattle and may rarely reach 100%. The case fatality rate in feedlot cattle is invariably associated with secondary bacterial tracheitis and bronchopneumonia and may reach 10%, but is usually no more than 1%. Morbidity and mortality are higher in feedlot cattle than in dairy herds because of the frequent introduction of susceptible animals into an enzootic situation. The case fatality rate in the systemic form of the infection in newborn calves is almost 100%.

Methods of transmission

The main sources of infection are the nasal exudate and coughed-up droplets, genital secretions, semen, and fetal fluids and tissues. Aerosol infection is the method of spread of the respiratory disease. Experimentally, the BHV-1 can be shed from calves into the environment and transported by air over a distance of at least 3.85 m to sentinel calves housed in a separate building.

Venereal transmission is the method of spread of the genital diseases. The virus may survive for up to 1 year in semen frozen at −196°C (−321°F).

Introduction of animals into a group often precedes an outbreak of the disease. However, it can arise simultaneously in a number of dairy farms in an area and spread from these to adjacent farms until the entire area is affected. The same pattern of occurrence simultaneously in a number of foci is seen in feedlots, and from these foci infection spreads to other pens in the lot. An outbreak usually reaches its peak in the 2nd or 3rd week and ends by the 4th–6th week.

To determine whether or not an infection in a herd will spread from a small inoculum, the number of secondary cases resulting from one infectious animal must be estimated. The ratio of secondary cases to originally infected animals is called the reproduction ratio and is commonly denoted by $R_0$. When $R_0 < 1$, the infection will not spread and the animal population is effectively protected from the infection. When the infection is established, but $R_0$ is reduced to less than one, the infection will disappear provided that some additional, commonly satisfied assumptions are met. When $R_0 > 1$, the infection can spread. Therefore, a strategy for controlling an infectious agent is effective when, and only when, the ratio for that strategy is less than one. The value of $R_0$ for a given host population is determined by a number of different factors including: the transmissibility of the infection; the period over which an infected host is infectious; the population density of hosts; and where appropriate, the density of vectors and the capacity of the vectors to transmit the infection.

Risk factors

Animal risk factors

Age and breed susceptibility

All ages and breeds of cattle are susceptible but the disease occurs most commonly in animals over 6 months of age, probably because of their greater exposure. There is no seasonal variation in incidence, except possibly a higher occurrence in feedlot cattle in the fall and winter months when large numbers of susceptible animals are assembled. The disease complexes associated with the virus occur most commonly in animals that lack acquired immunity from previous natural infection or vaccination. An unvaccinated herd of breeding cattle or a group of feedlot animals are highly susceptible to epidemics of respiratory disease and abortion. Newborn calves are highly susceptible to the systemic form of infection if the level of specific antibody to the virus in the colostrum is inadequate or if there is failure of transfer of passive immunity.

The analysis of the relationship between interferon genotype and severity of clinical disease in cattle experimentally inoculated with BHV-1 revealed that certain alleles of the interferon were significantly associated with the more severe clinical phenotype. A second allele at another locus was associated with the milder disease genotype. Thus, selective breeding programs aimed at altering the frequency of these alleles in cattle populations may potentially improve animal health and lessen the economic impact of BHV-1 infections.

Environmental and management risk factors

Several managemental factors have been associated with BHV-1 infection in a herd. Infected herds purchase cattle and participate in cattle shows more often than negative farms. The positive farms have more visitors and are situated closer to other cattle farms. The failure to vaccinate regularly and keep reliable records of vaccination dates are commonly associated with inadequate disease control.

In countries with BHV-1 eradication programs, the loss of certification is commonly associated with yearly number of cattle purchased, farm density within a 1 km radius, and cattle density within a 1 km radius.

Pathogen risk factors

The IBR-like viruses are now designated BHV-1, and the IPV-like viruses are designated BHV-12. With the latter subtype being further divided into two groups given the letter designations a and b.

Subtype 1.2a isolates cause abortion, 1.2b isolates are not abortifacient.

Subtype 1.3, or BHV-5, is the enzootic strain.

Inactivation of the thymidine kinase gene from BHV-1 reduces the abortifacient activity of the virus but does not eliminate the abortifacient activity of BHV-1. Currently available vaccines, which are made with 1.1 subtype vaccines, cannot be given to pregnant cattle because they are abortifacient. The currently available MLV BHV-1 vaccines can cause infertility in cattle infected 14 days after breeding.

The BHV-1 genome is not stable during host animal passage, and variations can occur in the restriction endonuclease patterns of the viruses within individual animals during both acute infections and after viral reactivation or after viral reactivation followed by superinfection with a different subtype of BHV-1 than was used for the primary inoculation.

The virus of IBR is similar to the virus causing IPV in cows and IJP of bulls. Manifestations occurring suggest that strains with differing tissue affinities may exist in the field, and slight differences can be detected by immunological and biochemical means. Only rarely do the respiratory and genital forms of the disease occur together. However, by routine methodology it is difficult, and usually impossible, to distinguish between isolates obtained from the reproductive tract and the respiratory mucosa. Likewise, with the exception of temperature-sensitive mutants, vaccine strains cannot be distinguished from field isolates.

The virulence of several strains of one genotype can vary widely. The outcome of BHV-1 infection can vary from subclinical to a systemic infection in neonatal calves that is often highly fatal. A subclinical infection of bulls in an artificial insemination unit with BHV-1 can last for several months, even in vaccinated animals. Vaccine strains of BHV-1 have been associated with outbreaks of meningococcalis in feedlot cattle with 7–10 days after routine vaccination intranasally with a vaccine intended for the intramuscular route.

Newborn calves under 3 days of age are susceptible to the highly fatal systemic form of IBR if vaccinated intramuscularly with a...
modified live virus BHV-1 and PI-3 vaccine.

Using DNA restriction endonuclease and polyacrylamide gel electrophoresis (PAGE) it is now possible to compare the antigenic differences between isolates obtained from different clinical syndromes, different species, tissues, and countries. Several different genotypes of the virus have now been identified, which may explain the emergence of a more severe form of the respiratory form of the disease in some countries as well as the different forms of the disease. The increasing number of BHV-1 isolates recovered in the United Kingdom, and the sudden increase in the incidence of IBR is probably due to the importation of a BHV-1 isolated within imported North American Holsteins. The Colorado and Strichen strains produced the characteristic clinical signs, whereas the Oxford strain produced a mild clinical response with minimal pathological lesions. Based on the evidence of epidemiology, molecular genotype analysis, and experimental pathogenicity, the more severe form of IBR that occurred in cattle in Britain in the mid-1970s was associated with BHV-1.1, which had a greater propensity for spread and was probably introduced in imported cattle. The herpesviruses isolated from reindeer is a distinct species within the family Herpesviridae.

Restriction endonuclease analysis of Australian BHV-1 isolates recovered between 1989 and 1993 revealed emergence of a new BHV-1 genotype, BHV-1.2b, which appears associated with severe respiratory disease. There is no evidence to date of the BHV-1.1 genotype in Australia. Outbreaks of IBR have occurred in feedlot cattle vaccinated against the infection. The causative viruses were mutants of BHV-1 which did not react with a monoclonal antibody specific for one of the epitopes on glycoprotein D, one of the most important antigens of the virus. An outbreak of a subclinical form of IBR has been described in a dairy herd of high health status and managed under high standards of biosecurity, and known to be serologically negative for the virus for the previous 15 years. Although 70% of the cows had seroconverted to the virus no clinical signs were observed with the exception of an ocular discharge in a few cows, and their performance and productivity were unaffected. The causative virus was isolated after reactivation with corticosteroids and had the DNA profile of a BHV-1 strain normally associated with severe respiratory disease.

The virulence of the virus or its host tissue specificity changes due to unknown factors. It has been suggested that the IPV was transmitted to North America from Europe in infected cattle, but continued to cause lesions in only the genital tract until its introduction into dense populations of cattle in feedlots encouraged rapid passage through many hosts and thus encouraged adaptation to the respiratory tract.

Restriction endonuclease DNA fingerprints of herpesviruses isolated from unrelated epidemics of bovine encephalitis have revealed that they are similar to each other, and totally different from BHV-1 and other ruminant herpesviruses. Though antigenically and genetically related to BHV-1, the bovine herpes encephalitis virus is distinctly different. A BHV-5 has been isolated from naturally occurring cases of non-suppurative meningoencephalitis in calves and can be reproduced experimentally.

The glycoprotein E (gE) gene is a virulence factor of BHV-1 is important in the development of gE-negative marker vaccines used in eradication programs. These marker vaccines, either inactivated or live-attenuated, are deleted in the gene coding for the non-essential glycoprotein E (gE) of BHV-1 in order to allow serological differentiation between vaccinated and infected cattle. A glycoprotein E-deleted BHV-1 strain has been isolated from cattle in the field.

**Immune mechanisms**

**Immunity to the virus is complex and consists of relationships between local and systemic antibody, and cell-mediated immunity.** Following natural infection or vaccination with the modified live virus (MLV) vaccines, both cell-mediated and humoral components of the immune system are activated. The level of humoral immunity has been used as an indicator of previous infection and an indirect measure of resistance to clinical disease. However, the level of serum neutralizing (SN) antibody is not a reliable indicator of resistance to clinical respiratory disease. Animals with low levels of antibody may be immune because of cell-mediated immunity. The level of cell-mediated immunity can be evaluated using the delayed-type hypersensitivity test. Experimentally, the virus-neutralizing (VN) titers are lower in calves inoculated with both the IBR and parainfluenza-3 (PI-3) viruses than in calves infected with a single virus. This suggests that mixed viral infections may result in greater immunosuppression, although infectious virus synthesis may be suppressed by interference.

Following intranasal infection or the use of a MLV IBR virus vaccine intra-nasally, local secretory antibody and interferon are produced. The interferon appears in 3 days and persists for 10 days. The presence of the interferon does not protect calves against experimental challenge 3 days after vaccination. However, the presence of even low levels of antibody in the serum or nasal secretion, which appears by day 7 following vaccination, provides varying degrees of resistance to clinical disease for 9 months.

**Colostral immunity**

Calves acquire colostral antibodies from dams with humoral antibody. The duration of the colostral immunity varies from 1 to 6 months of age dependent on the initial level acquired by the calf. Maternal antibody in the calf may interfere with the successful vaccination of calves before 6 months of age.

**Economic importance**

BHV-1 infection can cause major economic consequences in a dairy or beef cattle breeding herd, or in a beef feedlot. Losses are incurred due to epidemics of abortion, infertility due to IPV and IPB in bulls, loss of production and deaths from the respiratory form of the disease in all ages of cattle, deaths from the highly fatal systemic form of the disease in newborn calves, and the cost of treatment when secondary bacterial infections of the respiratory tract occur.

**PATHOGENESIS**

The virus causes disease through several different pathways including a primary infection restricted to the respiratory tract, eyes, and the reproductive tract. Systemic spread to many organs by viremia occurs as well as neuronal spread. In addition, the virus can establish latency in neuronal or lymphoid cells. Upon reactivation, the viruses re-establish the lytic cycle of replication.

**Respiratory disease**

The BHV-1 virus infects the nasal cavities and upper respiratory tract, resulting in rhinitis, laryngitis, and tracheitis. The pharyngeal tonsil is readily infected by the virus and may be an important lymphoid tissue for early anti-viral responses. There is extensive loss of cilia in the trachea leaving the tracheal epithelium covered by microvilli. Intratracheal administration of the virus results in almost complete denudation of tracheal columnar cells, which presumably has an adverse effect on the defense mechanisms of the respiratory tract. Spread from the nasal cavities to the ocular tissues probably occurs by way of the lacrimal ducts and causes conjunctivitis with edema and swelling of the conjunctiva, multifocal plaque formation on the conjunctivae, peripheral corneal edema, and deep vascularization. The
virus can also enhance the prevalence and severity of IBR in calves. In neonatal calves, potentially fatal infection, associated with the continued presence of viral antigen and active inflammation, contrasts with repair and clearance of viral antigen in weaning calves. Experimentally, the endobronchial inoculation of calves with the BHV-1 causes an interstitial pneumonia. The viral antigen can be detected in the desquamated cells and macrophages of bronchoalveolar fluid.

**Encephalitis**

The mechanism by which the brain is infected is presumed to be spread of the virus from the nasal mucosa via the trigeminal peripheral nerve to the trigeminal ganglion, resulting in a non-suppurative encephalitis. However, a viremia has been suspected. Severe encephalitis can be produced experimentally in colorostrum-deprived calves with neurovirulent type BHV-1. Experimental infection with BHV-1 produces respiratory disease and a mild encephalitis. Intranasal inoculation of young calves and adult cows with BHV-1 can result in non-fatal trigeminal ganglionitis and encephalitis, which may be an important mechanism for latent infection. A rabbit model has been used to study the neuropathogenesis of BHV-5 infection.

**Abortion**

Systemic invasion by the virus is followed by localization of the virus in several different tissues. The virus may be transported by peripheral leukocytes to the placenta and transferred to the fetus to cause abortion. The fetus is highly susceptible to the virus, which causes a peracute infection that is usually fatal. Infection in the last trimester of gestation may result in mummification, abortion, stillbirth, or weak calves with the usual lesions of IBR as well as the lesions of the stomachs and intestines that have been produced by experimental administration of the virulent virus to newborn calves.

The systemic form of the infection in newborn calves is characterized by severe inflammation and necrosis of the respiratory and alimentary tracts, including the pharynx, esophagus, lungs, larynx, lymph nodes, liver, and nephritis and encephalitis. There is severe laryngeal edema and respiratory distress which results in difficulty in swallowing and aspiration pneumonia. A severe, highly fatal syndrome characterized by diffuse erosion and ulceration of the upper alimentary tract, including the oral cavity, has occurred in beef feedlot cattle.

**Isolate or vaccination with an attenuated strain.** The virus may remain latent indefinitely and recrudescence, reactivation, and shedding of the virus can occur following the use of large doses of corticosteroids which mimic the effects of stress. Transport of cattle with latent infection can reactivate the virus, resulting in re-excretion of the virus and a rise in neutralizing antibodies. Attenuated vaccine strains can remain in a latent form at the time of vaccination. Vaccination also does not inhibit re-excretion of a wild strain that was in the latent form at the time of vaccination. The vaccine virus and the field isolates can be excreted after live virus vaccination and subsequent field isolate challenge. Colostral antibodies in calves do not prevent initial virus replication, and latency can persist after the decline in colostral immunity and the calves are seronegative. The location of latency of the virus in the body varies; the virus remains localized near the site of its first multiplication and during recrudescence will be re-excreted by the tissue primarily infected. The BHV-1 can be isolated from the trigeminal ganglion of clinically normal cattle during the latent period, and trigeminal ganglionitis can be observed during recrudescence.

**Latent infection with virulent BHV-1** virus may occur in the trigeminal ganglion of calves previously vaccinated with the MLV vaccine. The virulent virus may spread along the trigeminal peripheral nerve despite the presence of humoral antibodies in vaccinated calves. Recrudescence of the virus from the trigeminal ganglion and spread along the peripheral nerves by intra-axonal flow to the nasal mucosa can occur in calves treated with corticosteroids and, presumably, occurs following stress. The virus has been isolated from the trigeminal ganglia of 10% of clinically normal cattle at slaughter, 40% of which had SN antibody to the virus.

**The practical aspect of latency is that all cattle from endemic herds must be considered as potential sources of BHV-1 virus and capable of spreading infection to previously unexposed animals. Some latent carriers do not possess detectable antibodies. The only method of identification is by treatment with dexamethasone to initiate recrudescence and detection of the virus from nasal secretions, or the PCR examination of the trigeminal ganglion at necropsy.**

A combined serological and clinical surveillance of 20 dairy herds over three consecutive years revealed wide variations in the circulation of the virus. In some herds there was no identification of active infection, while in others one or two cycles of infection occurred in calves and yearlings, often without any clinical evidence of disease. Reactivation and shedding of the virus can occur in known carrier bulls at the time of mating, which may explain the higher incidence of titers in bulls than cows in some beef herds. Breeding bulls in an artificial insemination center were vaccinated with a MLV vaccine were shedding the vaccine virus in the semen, and the virus could be recovered from preputial washings 2–3 months after the last immunization. However, the frequency of recurrent infections and the amount of virus excreted are reduced after vaccination. The presence of passively acquired antibodies in calves does not prevent virus replication and establishment of latent infection. It is also possible to experimentally produce BHV-1 seronegative passively immunized calves which do not have antibody response after infection but develop a cell-mediated immune response after infection detected by a specific interferon gamma assay. The failure to easily detect such animals presents an epidemiological threat for the control of BHV-1 infections. Marker glycoprotein E-negative vaccines can also establish latency not only in naive but also in passively immunized neonatal calves after a single intranasal inoculation. This indicates that gE-negative vaccines, when used in calves with passive antibodies can result in seronegative vaccine virus carriers.

The experimental intrapulmonary infection of young bulls with BHV-1.2 caused acute balanoposthitis, latent infection, and detection of viral DNA in regional neural (sacral nerve ganglia, pelvic sympathetic plexus) and non-neural tissues (lymph nodes) 50 days after experimental reactivation. Following experimental infection in calves the BHV-5 also can result in latent infection of surviving animals.

Parturition may also be a stimulus for reactivation and shedding of a thermosensitive vaccine strain of the virus in vaccinated animals. Reactivation and shedding of the virus has also been observed in cattle that recovered from the respiratory form of the disease and 5 months later were experimentally infected with Dictyocaulus viviparus. The placenta may harbor the virus in a latent stage for up to 90 days without transmitting the virus to the fetus. Recrudescence may be differentiated from primary infection and re-exposure by the intranasal route based on the distribution of antiviral antibody activity among serum IgM, IgG1, and IgG2 isotypes.
Predisposition to pneumonia
The role of the virus in affecting the lung clearance mechanism of cattle in the pathogenesis of pneumonic pasteurellosis has been reviewed and is presented in the section on shipping fever pneumonia in cattle. Experimental aerosol exposure of calves with the BHV-1 virus impairs the function of alveolar macrophages, which allows Mannheimia haemolytica to persist in the lung and produce the characteristic lesion. In vitro studies indicate that the BHV-1 virus can interfere with the function of effector cells, such as macrophages, neutrophils, and lymphocytes. Aerosol exposure of calves to BHV-1 can affect the composition of alveolar phospholipids, which can alter the function of lung surfactant and compromise pulmonary defense mechanisms. The BHV-1 can cause alteration in the glycoconjugate composition of bovine nasal epithelial surfaces, which may promote Mann haemolytica proliferation in the early stages of pneumonic pasteurellosis. The virus also causes varying degrees of obstructive lung disease, resulting in increased resistance to breathing, retention of carbon dioxide, and increasing resting lung volume. Excessive airway constriction and impairment of bronchial relaxation occurs, which may compromise lung defense mechanisms and allow development of secondary bacterial pneumonia. A severe fatal BHV-1 pneumonia can occur.

Experimentally, active BHV-1 infection function affects bovine peripheral blood neutrophils, enhances the binding of Mannheimia haemolytica leukotoxin to bronchoalveolar leukocytes, and increases their killing. The virus increases the number of bronchoalveolar leukocytes, resulting in many more leukotxin-responsive cells being present in the lung.

Reproductive failure
The intrauterine inoculation of the BHV-1 into cattle results in an acute necrotizing endometritis in the uterine body and caudal portions of the uterine horns but minimal lesions in the anterior parts of the horns. Experimental inoculation of the virus into heifers on the day after estrus and insemination can result in lesions of the ova ries consisting of focal necrosis and cellular infiltration. Commercially available vaccinal strains of the BHV-1 virus can produce similar lesions. The ovarian lesions have marked effects on luteal function, and plasma progesterone values in the first estrus after inoculation are markedly lower than those in subsequent normal cycles. Whether the BHV-1 virus causes reproductive failure as a result of necrosis of the corpus luteum or embryonic infection remains to be determined. Recently hatched bovine embryos can be infected with any of several strains of BHV-1 and such infection in vitro is embryocidal. Experimentally induced infection during early pregnancy (7-28 days) will cause oophoritis and, in some cases, embryonic mortality. The effects of the virus on the genital tract and on reproductive performance in cattle have been reviewed.

Bovine mastitis
The BHV-1 and BHV-4 have been associated with mastitis in cattle. Both viruses, and including the foot-and-mouth disease virus, and the PI-3 virus have been isolated from milk. The BHV-4 has been isolated from cows with clinical mastitis which also developed antibodies against the virus at the time of the mastitis and no bacteria were isolated from the milk samples. Bovine umbilical cord endothelial cells were used to culture the virus. Experimentally inoculation of the ductus papillaris of the teat has resulted in replication of the virus and subclinical mastitis after BHV-4 infection. Simultaneous intramammary and intranasal inoculation of lactating cows with BHV-4 did not induce clinical but subclinical mastitis. It is unlikely that BHV-4 is a major mastitis pathogen.

CLINICAL FINDINGS
Rhinitis, tracheitis and conjunctivitis (red nose)
After experimental infection there is an incubation period of 3-7 days, but in infected feedlots the disease occurs 10-20 days after the introduction of susceptible cattle.

There is considerable variation in the severity of clinical signs following natural infection, dependent on the strain of the virus, the age susceptibility, and environmental factors. In North America, where the disease is endemic, the clinical disease is usually mild in dairy cattle and in range beef cattle. A severe form of the disease can occur in feedlots where crows and commingling from several sources occur. A severe form of upper respiratory tract disease and encephalitis have been reported in neonatal beef calves. There is sudden onset of anorexia, loud coughing, fever (up to 42°C, 108°F), severe hyperemia of the nasal mucosa, with numerous clusters of grayish foci of necrosis on the mucous membranes of the nasal septum visible just inside the external nares, a serous discharge from the eyes and nose, increased salivation, and sometimes a slight hypere excitability. A marked fall in milk yield may be the earliest indication in dairy cattle. The respirations are increased in rate and are shallow, but only an increase in the loudness of breath sounds are audible on auscultation of the lungs unless secondary pneumonia is present. A severe primary viral, or secondary bacterial, tracheitis may cause inspiratory dyspnea with abnormal tracheal breath sounds transmitted to the lungs. Respiratory distress is evident on exercise. A short, explosive cough is characteristic of some outbreaks but not in others. Sudden death within 24 hours after first signs appear can result from extensive obstructive bronchiolitis.

In dairy cattle, many animals in a herd become affected within a few days. The disease is usually mild, characterized by inappetence, coughing, profuse bilateral serous nasal discharge, excessive salivation, nasal lesions, moderate fever, and moderate drop in milk production, and recovery in a few days. Several animals may have the corneal form of the disease with obvious corneal edema, conjunctivitis, and profuse ocular discharge. The affected animals as a group do not return to full production for 10-14 days. The outbreak of respiratory disease will be followed by abortions in several days up to 90 days after the index case occurred.

In feedlot cattle the illness is often more prolonged, the febrile period is longer, the nasal discharge becomes more profuse and purulent, and the convalescent period is longer. Some deaths may occur in the acute febrile period, but most fatalities are due to a secondary bronchopneumonia and occur after a prolonged illness of up to 4 months in which severe dyspnea, complete anorexia, and final recumbency are obvious signs. Some recovered animals may have a persistent snoring respiration and a grossly thickened, roughened nasal mucosa accompanied by nasal discharge.

Ocular form of IBR
Conjunctivitis is a common finding in typical red nose, but outbreaks of conjunctivitis may occur as the major clinical finding. One or both eyes may be affected, which is easily misdiagnosed as infectious keratoconjunctivitis (pinkeye) associated with Moraxella bovis. However, the IBR lesions are confined to the conjunctiva and there are no lesions of the cornea except diffuse edema. The conjunctiva is reddened and edematous, and there is a profuse, primarily serous, ocular discharge. Calves less than 6 months of age may develop encephalitis, which is marked by incoordination, excitement alternating with depression, and a high mortality rate. Salivation, bellowing, convulsions and blindness are also recorded.
Systemic disease in newborn calves

In newborn calves under 10 days of age, the systemic form of the disease is severe and highly fatal. Sudden anorexia, fever, excessive salivation, and rhinitis, often accompanied by unilateral or bilateral conjunctivitis, are common. The oral mucous membranes are usually hyperemic, erosions of the soft palate covered by tenacious mucus are common, and an acute pharyngitis covered by tenacious mucopurulent exudate is characteristic. The larynx is usually edematous and respiratory distress is common. Bronchopneumonia is common, and loud breath sounds, crackles and wheezes associated with consolidation are present. Outbreaks of the disease commonly occur in highly susceptible herds where the herd immunity has declined, the dams are not vaccinated, and there is minimal, if any, vaccination even with safe vaccines may appear to be the cause of abortion if natural infection preceded vaccination. It is most common in cows that are 6–8 months pregnant. Retention of the placenta often follows, but residual infertility is unimportant. However, endometritis, poor conception and short estrus may occur after insemination with infected semen. The infectious bovine rhinotracheitis virus has been isolated from semen 12 months after storage.

Infectious pustular vulvovaginitis is characterized by frequent urination, elevation of the tail, and a mild vaginal discharge. The vulva is swollen, and small papules, then erosions and ulcers, are present on the mucosal surface. Mucosal ulcers may coalesce and sloughing of brown necrotic tissue may occur. Recovery usually occurs in 10–14 days unless there are complications.

Balanoposthitis is characterized by similar lesions of the glans penis and preputial mucosa.

CLINICAL PATHOLOGY

Virus isolation or detection

Isolation of the virus from nasal swabs using tissue culture, combined with a four-fold rise in antibody titers, between acute and convalescent phase sera are desirable for a positive diagnosis of the disease.1 When using nasal swabs, cotton and polyester swabs are recommended rather than calcium alginate swabs, which are viricidal within 2 hours. The virus can be detected in nasal swabs by the use of an ELISA, direct and indirect immunofluorescence technique, immunoperoxidase, and by electron microscopic examination which may reveal herpes-like viral particles. The sensitivity of the direct immunofluorescence technique is comparable to the cell culture technique. The ELISA is highly sensitive. A combination of the indirect immunofluorescence test and virus isolation from both ocular and nasal swabs of several animals will increase the recovery rate.1

The PCR assay is as sensitive as virus isolation and is a practical alternative for the rapid detection of the virus.1 The results are available in 1 day, compared to virus isolation which requires 7 days. Virus could be detected in nasal swabs for up to 14 days after experimental infection of cattle, and the assay can also detect the virus in bovine fetal serum and semen samples. The PCR assay can be used for detection of virus in semen and is considered equivalent to that of standard virus isolation and dot blot hybridization.51

The PCR assay with Southern blot hybridization is considered to be highly sensitive and can detect the virus in semen before they develop any detectable antibody.52 The PCR assay can also detect five times as many positive semen samples as the virus isolation on egg yolk–extended semen.53

Using restriction endonuclease analysis of viral DNA it is now possible to distinguish field isolates of the virus from vaccine strains, which may be useful in the investigation of vaccine-induced epidemics of the disease.

A PCR assay is used to screen large numbers of milk samples for the presence of BHV-4.54

Seroology

Several serological tests are available for the detection of antibody and a rise in titer between the acute and convalescent phases of the infection.

The primary immune response to BHV-1 experimental inoculation of cattle is characterized by the formation of IgM and IgG antibodies, primarily IgG1, by postinoculation day 7. Secondary immune responses are characterized primarily by the formation of IgG2 antibody. A secondary immune response resulting from abortion induced by intra-amniotic virus inoculation is characterized by a substantial increase in IgM antibody. A secondary BHV-1 exposure by the intranasal route does not result in secondary IgM antibody formation.

The VN test has been widely used and is the standard by which other techniques have been evaluated.55 The ELISA is a specific, sensitive, and practical test for detection of BHV-1 antibodies and has advantages over the SN test. The IgM-ELISA test is useful for the diagnosis of recent infection with BHV-1 in calves.56 A micro-ELISA test is being used for the control program of BHV-1 infection in Switzerland. The test is simple, rapid, and convenient compared to the SN test, which requires cell culture facilities and is time-consuming.

The detection of latent BHV-1 infection in cattle is important in control programs and in international trade activities. Therefore, tests to detect specific antibodies in serum must be highly sensitive in order to detect low levels of BHV-1-specific antibodies.57 This emphasizes the need for international standardization of tests to detect BHV-1-specific antibodies in cattle. In a comparison of European laboratories to evaluate a panel of test sera, including negative, weak and strong positive samples as well as international reference sera, VN tests and ELISAs demonstrate high specificity.58 The quality of most laboratories was adequate. The VN test and the gB-specific ELISAs were most sensitive for the detection of antibodies in serum; the indirect ELISAs are the tests of choice for assaying milk samples. Most of the ELISAs demonstrate 100% specificity. Discrepancies occur with the low amounts of specific antibody. An indirect ELISA using undiluted test serum demonstrated 100% sensitivity. A commercial anti-BHV-1 blocking ELISA test kit is available to differentiate between cattle immunized with a marker BHV-1 vaccine and naturally infected cattle, but the sensitivity is only 74%.58

An immunofluorescence assay using monoclonal antibodies can discriminate between the four ruminant alphaherpesviruses related to the BHV-1.1

They include the bovine herpesvirus-5, caprine herpesvirus-1 (CpHV-1), cervine herpesvirus-1 (CvHV-1), and cervine herpesvirus-2 (CvHV-2). Buffalo herpesvirus-1 and elk herpesvirus are also closely related to BHV-1.4

Four serological tests have been evaluated to detect serum Colostral antibodies to BHV-1 in calves.56 A blocking ELISA demonstrated superior sensitivity in the detection of antibodies in calves up to 9–11 months of age compared to calves up to 7 months of age.59

The serological tests used for the BHV-1 eradication programs in The Netherlands
have been compared. The combination of the g6-ELISA (for screening), and the Danish test—a blocking and indirect ELISA (for confirmation), provides a sensitivity of >99.0% and a specificity of >99.9%. Bulk tank milk testing for BHV-1 antibodies may be useful in eradication and monitoring programs because it offers the possibility of rapid and inexpensive screening. The correlation between the bulk milk test and the within-herd prevalence of seropositive animals can be as high as 0.86. If BHV-1 is detected in the bulk milk, there is a high probability that more than one animal in a herd is infected and that the infection has spread. The BHV-1 blocking ELISA is in use on bulk milk samples as part of the Danish surveillance system for BHV-1 infection in dairy herds. The test can detect seropositive herds, with prevalence proportions as low as one seropositive cow out of 70 cows. Specific antibody against BHV-1 may be detectable in fetal fluids and increases the rate of diagnosis of abortion.

**NECROPSY FINDINGS**

In adult cattle, gross lesions are restricted to the muzzle, nasal cavities, pharynx, larynx and trachea, and terminate in the large bronchi. There may be pulmonary edema or secondary bronchopneumonia, but for the most part the lungs are normal. In the upper respiratory tract there are variable degrees of inflammation, but the lesions are essentially the same in all anatomical regions. In mild cases there is swelling and congestion of the mucosa. Petechiae may be present and there is a moderate amount of purulent exudate. In severe cases the exudate is profuse and fibrinopurulent. When the exudate is removed, the mucosa is intact except for small numbers of necrotic foci in the nasal mucosa but there may be diffuse denudation of epithelium in the upper part of the trachea. Lymph nodes in the throat and neck region are usually swollen and edematous. Histologically, there is acute, catarrhal inflammation of the mucosa. Petechiae may be present in the submucosa and are rare in experimental infections. Histologically, there is acute, catarrhal inflammation of the mucosa. Petechiae are rarely seen in natural cases but do occur transiently in the nuclei of respiratory epithelial cells in experimentally infected animals. Secondary bacterial invasion will cause a more severe necrotizing change, which is usually followed by the development of bronchopneumonia. The virus is usually isolated from affected tissues using cell culture techniques. It can also be demonstrated in paraffin-embedded tissues by utilizing immunohistochemical techniques.

In the systemic form in neonatal calves, severe epithelial necrosis has been observed in the esophagus and rumen, the adherent necrotic epithelium having the pultaceous quality of milk curd. The laryngeal mucosa is congested and edematous, with multiple focal lesions in the mucosa. Bronchopneumonia is common with a thick white exudate coating the tracheal lumen and extending into the bronchi. Histologically, there is necrosis of the pharynx, larynx, associated lymph nodes, esophagus, and liver. Inclusion bodies are evident in many surviving epithelial cells.

**Aborted fetuses** show moderately severe autolysis and focal necrotizing hepatitis. Microscopically, foci of necrosis rimmed by very few leukocytes are visible in the liver and many other organs. Occasionally, intranuclear inclusion bodies can be seen. Viral antigen can be demonstrated in sections of the lung, liver, spleen, kidney, adrenal gland, placentae, and in mummified fetuses using the avidin–biotin complex system. Using this system, the viral antigen can be found in fetal tissues from which virus could not be isolated in cell culture. The **encephalitic form** lacks gross lesions but is characterized microscopically by non-suppurative inflammation, neuronal degeneration and gliosis, located particularly in the cerebral cortex and the internal capsule. Inclusion bodies are sometimes present. Both immunoperoxidase and PCR tests are capable of detecting BHV-5 antigen in formalin-fixed brain tissues affected with bovine herpesviral encephalitis.

**Samples for confirmation of diagnosis**

| Histology | Formalin-fixed samples: abortion/neonate: lung, liver, trachea, kidney, adrenal gland, rumen, esophagus, pharynx; respiratory form: nasal turbinate, trachea, pharynx, lung; encephalitic form: half of midsagittally-sectioned brain (LM, IHC) |
| Virology | Abortion/neonate: lung, liver, kidney, rumen; respiratory form: lung, trachea, nasal swab; encephalitic form: half of midsagittally-sectioned brain (FAT, ISO, PCR) |

**DIFFERENTIAL DIAGNOSIS**

Infectious bovine rhinotracheitis is characterized by acute rhinotracheitis, coughing, profuse nasal discharge, nasal septum lesions, bilateral conjunctivitis, anorexia, fever, and gradual recovery in a few days. Secondary bacterial tracheitis and pneumonia can occur. It must be differentiated from the following:

- **Pneumonic pasteurellosis** is characterized by marked toxemia and depression, coughing, anorexia, depression, fever, abnormal lung sounds, good response to antimicrobials.
vaccinated and depend on natural exposure. Vaccination is therefore recommended in areas where the prevalence of infection is high and eradication is not feasible because of the extensive nature of the cattle population and movement of animals from one area to another.

Biosecurity

Biosecurity is any practice or system which prevents the spread of infectious agents from infected animals to susceptible animals or which prevents the introduction of infected animals into a herd, region or country in which the infection has not yet occurred. Biosecurity is an integral part of any successful livestock enterprise, and reduces the risks and consequences of introducing an infectious disease. The components of biosecurity, include management and placement programs, farm layout, decontamination, pest control, and immunization. All of these factors directly affect productivity and profitability.

The introduction of new infections into herds can be prevented or minimized by purchasing animals directly from herds known to be free of a particular disease. The adoption of this principle requires awareness of the possibility of purchasing unknown infected animals and testing animals for the infection before entry into the herd. It may also require keeping the introduced animal in quarantine for several weeks after arrival before it is mixed with the other animals.

Veterinarians need to work with their clients to develop a specific disease control and biosecurity protocol for each farm. The benefits of a rigidly enforced biosecurity program need to be stressed. Veterinarians can assist producers in developing methods to handle livestock and to purchase replacement stock by designing protocols which concentrate on general and specific aspects, such as design and construction of isolation rates.

Closed herd. A closed farming system to prevent the introduction of infectious diseases into dairy farms is technically possible and is economical. A closed dairy farming system could prevent the introduction of BHV-1 and can be a good starting point for eradication of infectious diseases from the herd.

In the cattle industry, animals are moved freely from their farms of origin to veterinary clinics, cattle shows and sales, auction markets, 4H club events, and community grazing pastures. Cattle are commonly returned to their farms of origin after being at shows and sales, veterinary clinics and other events where animals from other farms are mixed. Animals may come mingle with those from adjacent herds (broken fences or cattle breaching fences from one pasture to another). Breeding bulls may be leased from their farm or origin, used on another farm, and then returned to the farm of origin. The mixing of animals which occurs in all of the above circumstances provides opportunities for the transmission of important infectious agents.

Biosecurity of veterinary practices and veterinary teaching hospitals is now an important aspect of health management of food producing animals.

Vaccination

With currently available diagnostic tests, it is not possible to identify animals which have a latent BHV-1 infection. The next best strategy is to use a well-planned vaccination program.

Rationale for vaccination

The rationale for vaccination is based on the following:

- The virus is ubiquitous and the occurrence of the disease unpredictable
- Economic losses from abortion, neonatal disease, and respiratory disease can be high
- Colostral immunity in calves wanes by 4–6 months of age
- The vaccine will prevent abortions due to the virus and provide protection against respiratory disease if given at least 10 days before natural exposure.

Both the aerosol and IM administration of a virulent strain of the virus to colostrum-deprived seronegative cattle (6–12 months of age) results in comparable levels of serum antibody, but no measurable nasal secretory antibody. When these same cattle are challenged later by aerosol exposure they are protected from clinical disease and nasal secretory antibodies will develop.

Conventional vaccines

Based on the effectiveness of active immunization following natural exposure, both MLV and inactivated virus vaccines have been available.

Modified live-virus vaccines. There are two types of MLV vaccines. One is the parenteral Vaccine usually made with bovine fetal kidney tissue culture, and the other is an intranasal vaccine of rabbit tissue culture origin. An intranasal vaccine of bovine tissue culture origin is abortigenic, especially in non-immune cows. The intranasal vaccine provides protection against respiratory disease induced by experimental challenge 72 hours after vaccination. In general, the intranasal vaccine provides effective protection against the respiratory form of the disease but occasionally disease occurs in vaccinated animals. The intranasal vaccines do not cause a significant systemic reaction, and have been used in the face of an outbreak where all in-contact animals are vaccinated in an attempt to reduce the number of new cases.

A major requirement of the intranasal vaccine is that the vaccine virus must multiply on the nasal mucous membranes. If the vaccine is not administered into the nasal cavities carefully, or if the animal is difficult to handle or snorts out the vaccine, vaccination will not occur. The careful administration of a temperature-sensitive vaccine in 2 mL of diluent into one nostril is as effective as a two-nostril vaccination method using a total of 5 mL of diluent. The pre-existence of some local antibody from natural exposure or co-infection with a virulent strain of the virus may also restrict the multiplication of the vaccine virus, especially the temperature-sensitive mutants.

Temperature-sensitive BHV-1 MLV

-A intranasal BHV-1 vaccine containing a MLV strain whose growth is restricted to the upper respiratory tract has been developed in Europe. The vaccine strain is chemically treated to produce a temperature-sensitive characteristic, so that it cannot replicate at the body temperature of the animal. Prebreeding vaccination of replacement heifers with the vaccine provides fetal protection. The vaccine is efficacious and safe for use in pregnant cattle. Intranasal vaccination
stimulates both systemic and local cell-mediated immunity and antibody. Dairy cows develop antibodies within 2 months after the vaccination, and 30 months later 91% of the vaccinated animals that responded still had detectable antibodies. A percentage of unvaccinated animals may also seroconvert suggesting, but not proving that vaccine virus has been transmitted to them. Thus vaccine-induced antibodies may persist for years and interfere with control programs that are based on serological monitoring.

Disadvantages of MLV vaccines – The extensive use of MLV vaccines has reduced the incidence of clinical disease but there are some potential disadvantages. MLV vaccines must be stored and handled properly to avoid loss of potency. The parenteral MLV vaccine is potentially abortogenic and cannot be used on non-immune pregnant cattle. The virus in MLV vaccines can also become latent following vaccination. Fatal, generalized BHV-1 infection has been associated with vaccination of beef calves under 3 days of age with MLV containing BHV-1 and PI-3.27 An outbreak of meningencephalitis occurred in purchased Holstein-Friesian male calves vaccinated intranasally at 1 and 3 weeks of age with a commercial MLV vaccine containing BHV-1, bovine virus diarrhea virus (BVDV), PI-3, bovine adenovirus infection type-7 and bovine respiratory syncytial virus (BRSV).26 Parenteral vaccination was recommended as the proper vaccination protocol. The isolated virus was classified as BHV-1.I.26

Shedding of virus by vaccinated animals – There is some concern that vaccinated calves may shed the vaccine virus, which could then spread to pregnant cattle resulting in abortion. In calves vaccinated with the intranasal vaccines, the virus replicates in the respiratory tract and is shed for 7–14 days. In non-immune calves, replicating virus can be detected 9 hours after vaccination, with peak shedding occurring at 4 days. However, the intranasal vaccination of feeder calves at 7 months of age does not result in transmission of the vaccine virus to non-vaccinated animals co-mingled with the vaccinated. Calves vaccinated with a live temperature-sensitive mutant of BHV-1 vaccine were protected against clinical illness from experimental challenge, but excreted the virus 2 months later following treatment with corticosteroids. This emphasizes the general principle that the use of an MLV vaccine implies a continuing commitment to vaccination which may reduce the incidence of disease but is unlikely to eradicate the infection.

Inactivated vaccines. Inactivated virus vaccines were developed because of some of the disadvantages of MLV vaccines. They do not cause abortion, immunosuppression or latency, although they do not prevent the establishment of latency by field strains. They do not cause shedding and are safe for use in and around pregnant animals. They are also relatively stable in storage. Inactivated vaccines, however, may not be as efficacious as MLV vaccines because of the potential for destruction of some of the protective antigens during the inactivation process. They require two doses of the vaccine and protection is not observed until 7–10 days following the second dose of the vaccine which is usually given 10–14 days after the primary vaccination.

A major disadvantage of both the MLV and inactivated vaccines is that neither allows for differentiation between vaccinated and naturally infected animals. These factors render conventional vaccines ineffective for a concurrent vaccination and eradication strategy, as well as inappropriate for use in breeding bulls for export market or artificial insemination units which demand BHV-1-free animals. These limitations, along with major advances in molecular biology and protein purification techniques, have encouraged the development of genetically engineered attenuated vaccines as well as nucleic acid-free subunit vaccines.

Subunit vaccines. A subunit vaccine contains only one or more of the antigens of the pathogen necessary to evoke protective immunity, and lacks the components that might cause unwanted side-effects.39 The major surface glycoproteins of the BHV-1 are the antigens responsible for stimulating protective immunity. To produce a subunit vaccine containing only surface glycoproteins, the proteins are isolated from the virus of virus-infected cells, or the peptides can be synthesized. The major glycoproteins of BHV-1 originally designated gL, gIII and gIV are now named gB, gC, and gD,40 and they induce high levels of antibody in cattle that are fully protected from experimental disease. The level of immunity based on serum antibody titers and protection against experimental challenge is much greater with the individual glycoproteins than are those immunized with commercially available inactivated vaccines.

BHV-1 subunit vaccines provide a number of advantages:

- Serological assays, based on one or more antigens not present in the vaccine provide a potential to differentiate vaccinated from naturally infected animals.

Prevention of infection by the use of a BHV-1 subunit vaccine combined with the use of a diagnostic test to identify infected cattle, offers the potential for vaccination of breeding bulls for artificial insemination units and export, as well as for eradication of the virus.

The potential disadvantages of subunit vaccines include:

- Because of the amount of glycoprotein needed, two immunizations may be necessary for protection
- Subunit vaccines will have to be compatible with the commonly available multivalent vaccines
- The efficiency of subunit vaccines is highly dependent upon the use of an effective adjuvant.

An experimental subunit vaccine containing truncated BHV-1 glycoprotein protected beef calves vaccinated at 3 and 7, or at 6 and 7, months of age from experimental aerosol infection with BHV-1, 12 days after the second vaccination. Vaccinated calves had higher levels of SN antibodies and nasal antibodies than control.70 Low levels of maternal antibodies did not interfere with the antibody response of calves to two-dose vaccination at 4 and 5 months of age. The level of protection was similar in calves vaccinated at 3 and 7, or at 6 and 7 months of age, which suggests that calves can be primed with the first vaccination at an early age and respond well to revaccination at weaning. This provides a management strategy of the first vaccination at spring branding, and the second vaccination at weaning. The nasal and serum antibody levels in calves vaccinated at 3 and 4 months of age declined to negligible levels 3 months later which may be a disadvantage.

A subunit BHV-1 vaccine containing only the virus glycoprotein IV along with a recombinant Mann. haemolytica vaccine was compared with a MLV BHV-1 vaccine for the prevention of respiratory disease in feedlot calves.71 The subunit vaccine was considered superior to the MLV BHV-1 vaccine in reducing mortality due to respiratory disease.

Marker vaccines. A marker vaccine is based on deletion mutants of one or more microbial proteins, which allows the distinction between vaccinated and infected animals based on respective antibody responses.72 A marker vaccine must be accompanied by a diagnostic test,
which enables distinction of infected from vaccinated animals. These tests detect antibodies against a glycoprotein that is lacking in the vaccine. The desirable characteristics of the companion diagnostic test include:

- Antibodies detectable in 2–3 weeks after infection, both in vaccinated and unvaccinated cattle
- Antibodies must persist for at least 2 years, preferably lifelong
- A low level of virus replication gives rise to detectable antibody formation
- Cattle repeatedly given the matching marker vaccine remain negative in the test
- The test should be suitable to detect antibodies in milk
- A high sensitivity and specificity in comparison with conventional antibody tests

Mutants of BHV-1 have been developed by deleting one or more of the non-essential glycoproteins. Marker vaccines offer the advantage of evaluating the effect of vaccination on the circulation of the field virus under naturally occurring conditions. In a randomized clinical field trial the incidence of infection can be determined by measuring the number of cattle that develop antibodies against gE during the experimental period. Vaccination of calves with a glycoprotein E-negative vaccine for BHV-1 was effective in reducing both the clinical signs and the excretion of challenge virus as early as 7 days after IM vaccination, or 3 days after intranasal vaccination.

Experimental results demonstrate the efficacy of the potential marker vaccines. A thymidine kinase-deficient gC deletion mutant protected calves against disease and reduced shedding of virus following challenge. A double vaccination with a killed gE-negative vaccine prevented clinical disease after challenge infection, and the duration peak of virus shedding was significantly reduced. An intranasal vaccination with a live gE-negative vaccine reduced the challenge virus replication following contact challenge 2 days after vaccination. A double vaccination with an experimental subunit gD BHV-1 vaccine was highly efficacious in preventing clinical signs after challenge, but also prevented replication and subsequent excretion of the challenge virus. In some cases, the inactivated BHV-1 marker vaccine is more efficacious in reducing virus excretion after reactivation than a live marker vaccine.

Using a gE-deleted BHV-1 strain, both a killed virus and MLV marker vaccine have been developed. These vaccines induce all the relevant immune responses against BHV-1-specific immune reactions, including antibodies against gE. Both vaccines have the capacity to reduce, and even to stop, the spread of BHV-1. A serological test that detects gE-specific antibodies in serum and milk is also available. These vaccines have been tested according to the current European requirements for the development of bovine vaccines. The live vaccine is safe in pregnant cattle and is considered safe for all kind of breeding cattle, including bulls. The live virus marker vaccine is also efficacious in the presence of maternal antibody, and vaccination of very young calves, irrespective of their BHV-1 status, can be recommended. An inactivated BHV-1 gE-negative vaccine resulted in only a slight decrease of about 1.4 liters per cow in milk production after a double vaccination.

**Combination or multivalent vaccines.** The vaccines available for the control of diseases associated with BHV-1 infection are mostly multivalent antigen vaccines containing other respiratory pathogens such as PI-3, BRSV, and BVDV. Some also contain the antigens for the control of leptospirosis and campylobacteriosis. Vaccines containing only the BHV-1 are not in common use. A Canadian field trial to compare the serological responses in calves to eight commercial vaccines against BHV-1, PI-3, BRSV, and BVDV found some differences. Antibody responses to BHV-1 were higher in calves vaccinated with MLV vaccines than in those vaccinated with the inactivated vaccines. There were no differences in seroconversion rates and titers to BHV-1 between intranasal and MLV IM vaccines following a single vaccination. However, after double vaccination with MLV BHV-1 vaccines, both seroconversion rates and changes in titers to the virus were higher in calves vaccinated IM than in those vaccinated intranasally. Whether or not these differences in antibody titers reflect differences in vaccine efficacy against naturally occurring disease in the field situation is unknown.

The vaccination of calves with multivalent vaccines containing MLV or MLV and inactivated BHV-1 is associated with virus-specific interferon gamma production and protection from clinical disease due to challenge 5 days after a single vaccination.

**Immunization and latency.** Immunization with vaccines, as with natural infection, does not prevent subsequent infection and the possibility of latency.

**Vaccination programs in herds.**

**Beef breeding herds.** Beef calves should be vaccinated 2–3 weeks before weaning as part of a preweaning preconditioning program. Calves vaccinated with the parenteral MLV BHV-1 vaccine before colostral BHV-1 antibody titers reach low levels do not develop an immediate, active serological response, as indicated by serological titers, but are sensitized to the virus. Revaccination at a later date, when maternal antibodies have decreased to undetectable levels, results in a marked serological response. Heifer and bull replacements are vaccinated at least 2 weeks before breeding. When outbreaks of the respiratory disease occur in unvaccinated beef herds, all cattle in the herd may be vaccinated with the intranasal vaccine. Whether or not beef herds should be vaccinated annually following the initial vaccination is uncertain. There are field reports of outbreaks of abortion due to the virus in beef cattle that were vaccinated 3 years previously, which suggests that revaccination of breeding females every 2 years may be indicated. Since both natural infection and vaccination results in latent infection it may be that the persistence of the virus, combined with natural exposure, may result in persistence of antibody. The duration of protective immunity following vaccination is uncertain, but usually lasts 1 year. Antibodies last for at least 5.5 years in heifers following experimental infection and complete isolation during that time.

The MLV BHV-1 vaccine given intranasally or parenterally can enhance the prevalence of infectious bovine keratoconjunctivitis in beef calves vaccinated between 4 and 10 months of age, when the risk for the ocular disease is highest. The explanation for the pathogenetic mechanism is uncertain.

**Feedlot cattle.** Feedlot cattle should be vaccinated at least 10 days before being placed in the lot, especially one in which the disease may be enzootic. If this is not done a high incidence of the respiratory form of the disease may occur in recent arrivals. If vaccination before arrival is not possible, the next best procedure is to vaccinate the cattle on arrival and place them in an isolation starting pen for 7–10 days during which time immunity will develop.

**Prevention of pneumonia.** A field trial of pre-shipment vaccination of cattle with a combination BHV-1 and PI-3 vaccine administered intranasally 3 weeks before shipment from western Canada to Ontario did not have a significant effect on treatment rates of the animals for pneumonia after their arrival in the feedlot. The vaccination trial was designed to examine the hypothesis that vaccination with a BHV-1 virus vaccine prior to the stress of shipment would decrease the incidence of bovine respiratory disease, most of which is pneumonic pasteurellosis.
Experimentally, vaccination of cattle with the BHV-1 virus vaccine prior to inoculation with an aerosol of BHV-1 virus, followed later by an aerosol of Mannhaemolytica, provides protection against the bacterial pneumonia. There was no significant difference between vaccinated and non-vaccinated animals in terms of liveweight gains and incidence rate of subclinical disease. A commercially available MLV BHV-1 intranasal vaccine has been used in veal calves for this purpose but the lack of controls makes it difficult to interpret the results.

Dairy cattle. The necessity of vaccinating dairy cattle will depend on the prevalence of the disease in the area and in the herd, and the movement of cattle in and out of the herd. A closed herd may remain free of BHV-1 infection indefinitely and vaccination may not be indicated. But to avoid unpredictable abortion storms due to the virus in dairy herds, heifer replacements should be vaccinated for the disease 2–3 weeks before breeding. Vaccination of a large dairy herd with a persistent BHV-1 infection has been successful in controlling the respiratory form of the disease. The intranasal vaccine has been used extensively in newborn calves in problem herds, but its efficacy at such an age is unknown. The parenteral vaccination of beef calves under 3 days of age with a MLV BHV-1 and PI-3 vaccine caused high mortality. If the systemic form of the disease poses a threat to a potential calf crop, the pregnant cows could be vaccinated with the intranasal vaccine in late pregnancy; this will increase the level of colostral antibody available to the newborn calf and will provide newborn calves with protection against the highly fatal systemic form of the disease.

Bulls intended for use in artificial insemination centers present a special problem of disease control because the virus in semen can have severe consequences on reproductive performance. Bulls that are seropositive to the virus must be considered as carriers and potential shredders of the virus, and should not be allowed entry to these centers. Not all bulls that are seronegative can necessarily be considered free of the virus, and regular attempts at the identification of cattle infected with the wild-type BHV-1 wild-type strains express gE. These so-called marker vaccines or 'diva' (differentiating infected from vaccinated animals) vaccines allow the identification of cattle infected with the wild-type BHV-1 within a vaccinated population using a gE-ELISA or a commercially available gE-blocking ELISA (Idexx) which both specifically detect gE antibodies. The eradication program is based on the presumption that all BHV-1 wild-type strains express gE and induce antibodies which can be measured with a gE-blocking ELISA.

Eradication

Eradication of the BHV-1 virus from a single herd or the cattle population in a country can be considered as an alternative to vaccination. One of the prerequisites for the exportation of pedigree cattle is that the animals are serologically negative, which requires that the herd be free of infection with BHV-1. With careful planning and health management, it is possible to establish a seronegative herd. In a preliminary study in one closed beef herd in which there was latent BHV-1 infection, the calves were raised in isolation separate from the cows, following weaning. All of the maternally derived BHV-1 titers in the calves decayed to zero at weaning time and remained seronegative while raised in isolation. Serologically positive animals are removed or culled, and only seronegative animals introduced into the herd. In 1983, Switzerland began a national program for the eradication of IBR. The disease was made notifiable and the use of vaccination was prohibited. The program is based on:

- Annual serological testing of the national herd
- Restrictions on the trade with seropositive animals
- First priority of eradication was given to farms with breeding animals
- Stepwise elimination of seropositive animals.

By 1987, the breeding stock was virtually free of IBR. The virus was also eradicated from a beef feedlot farm in Switzerland that raised 750 calves over a period of 12–13 months for market at 500 kg BW. Seropositive animals were identified serologically, kept separate from seronegative animals, and monitored serologically every 3 months. Eradication was complete within 9 months.

In other countries, control is being attempted by segregation and elimination of seropositive animals and reduction of animal movement to prevent spread. This approach is not feasible in countries with extensive cattle populations and where management practices result in movement of cattle from one region to another.

Eradication using marker vaccines.

Some countries are beginning an immunization program with the marker vaccines, which will protect the cattle against disease but still allow differentiation between vaccinated animals and those that have been naturally infected and are potential carriers of the latent virus. These infected animals could be eliminated over a period of time. Successful eradication depends not only on the efficacy of the vaccine but also on the quality of the tests. False-positive test results can lead to unnecessary culling of cattle, an increase of costs, and reduced co-operation of farmers in the eradication program.

In The Netherlands, a compulsory eradication program for BHV-1 began in 1998. The program required that farms either vaccinate all cattle twice yearly or be approved for a certified BHV-1 free status — or SPF (specific pathogen free). To become a certified BHV-1 free herd, cattle have to be sampled individually and all seropositive animals culled as soon as their status is known. The BHV-1 free herd status is monitored by monthly bulk milk samples. The spread of BHV-1 between herds can be prevented using a surveillance system of sampling herds annually, both individual milk samples and blood samples.

Herds with BHV-2 infected (seropositive) animals are required to vaccinate with a glycoprotein E (gE)-negative BHV-1 vaccine. The vaccine may be either an inactivated or live vaccine both based on a spontaneous BHV-1 mutant without the complete gE gene. These so-called marker vaccines or 'diva' (differentiating infected from vaccinated animals) vaccines allow the identification of cattle infected with the wild-type BHV-1 within a vaccinated population using a gE-ELISA or a commercially available gE-blocking ELISA (Idexx) which both specifically detect gE antibodies. The eradication program is based on the presumption that all BHV-1 wild-type strains express gE and induce antibodies which can be measured with a gE-blocking ELISA.

The success of the marker vaccines depends on their capability to reduce transmission of the virus in the field. To prevent major outbreaks on a farm, the transmission ratio R0 between animals must be below 1. If the Ro between animals is below 1 on all farms eradication of BHV-1 would be certain. However, even when Ro between animals is not below 1, eradication can still occur when the Ro between herds is below 1, because the reduced transmission within a farm, makes farms less susceptible and less infectious. For BHV-1 it is possible that vaccination with a live gE-negative vaccine would reduce Ro in a herd below 1.

The efficacy of a live E-negative BHV-1 vaccine to reduce the transmission of BHV-1 in cattle was evaluated in a randomized, double blind, placebo-
controlled field trial in 84 dairy herds in the Netherlands. The incidence of BHV-1 infections during 17 months was monitored by detecting antibodies against glycoprotein E. The transmission ratio \( R_0 \) in the placebo-treated herds was estimated at 25 and 12 in the vaccinated herds. Thus the use of the live gE-negative BHV-1 vaccine reduces the incidence and transmission of infection in the field.

Before the eradication program began, a large field trial to evaluate the efficacy of the live gE-negative BHV-1 vaccine found that some placebo herds, which were not vaccinated, were seronegative for gE-negative BHV-1, but seropositive for BHV-1 by glycoprotein B (gB) blocking ELISA. The source of the gB seropositive occurrence was undetermined. Antibodies against BHV-5 may be differentiated from those of BHV-1 in a BHV-1 glycoprotein E blocking ELISA. The gE-negative BHV-1 vaccine strain is not re-excreted after virus (BVDV) type 2 was found in the field. The incidence of BHV-1 using the marker vaccine. In February it was compulsory for Dutch cattle farmers to take measures to control BHV-1. Between May 1, 1998 and February 22, 1999 it was compulsory for Dutch cattle farmers to take measures to control BHV-1. Cattle on farms not already certified as BHV-1 free had to be vaccinated twice yearly with a gE-negative BHV-1 marker vaccine. In February 1999, the Dutch Animal Service advised all veterinary practices to postpone vaccination against BHV-1 using the marker vaccine. Severe disease had occurred in herds vaccinated with the marker vaccine. Using monoclonal antibodies, bovine virus diarrhea virus (BVDV) type 2 was found in the vaccine batch. Batches of vaccine which contained the BVDV type 2 induced clinical signs of BVDV when inoculated into susceptible animals. The first clinical signs of illness occurred 6 days after vaccination. Morbidity was up to 70%; on some farms none. During the first week feed intake and milk production decreased. In the second week, some animals become severely ill with fever, nasal discharge, and diarrhea. By the third week the number of affected animals increased rapidly and some died. Necropsy findings included erosions and ulcers of the digestive tract. Contamination of the marker vaccine with the BVDV was a consequence of infection of fetal calf serum used in vaccine manufacture. Vaccination of calves with a BHV-1 marker vaccine containing BVDV type 1 did not induce clinical disease. By the end of 1999, 6997 cattle farmers had lodged complaints related to the vaccine. During the compulsory vaccination period, 13% of the herd vaccinations resulted in clinical disease and complaints. Following recognition of the outbreaks associated with the marker Vaccine some dairy farmers identified a 'chronic wasting' syndrome in their cows which they attributed to the vaccine. Field investigations of these cases could not associate them with the vaccine. A review of the research into the chronic wasting syndrome of dairy cows found no evidence to associate the syndrome with the vaccine. Vaccination of pregnant heifers in their third trimester experimentally with a high dose of the marker vaccine did not have any adverse effects. Comparison of performance of dairy herds which were or were not vaccinated with the marker vaccine in 1998 could not discern any differences due to the vaccine.

**Loss of certification.** The probability of and risk factors for the introduction of BHV-1 into SPF Dutch dairy farms has been examined. A total of 95 SPF dairy farms were monitored for 2 years during which time 14 introductions of infectious diseases occurred on 13 of the 95 farms for a total incidence rate per herd-year at risk was 0.09. Outbreaks were usually associated with allowing cattle to return to their farm, more often grazed cattle at other farms, and less often provided protective clothing to the veterinarian. For a successful eradication program, farms should remain BHV-1 free which can be achieved by a more-closed farming system. A more-closed farming system is one which rules out the possibility of direct contact with other cattle from other farms. Also, the farmer requests that professional visitors like veterinarians and AI technicians to wear protective farm clothing when handling cattle. Protective farm clothing are coveralls or overcoats and boots which can be worn over ‘off-farm’ clothing and which the farmer provides to the visitors before handling cattle. A sanitary barrier is a covered area outside the barn in which visitors put on their ‘off-farm’ clothes. A sanitary barrier is a covered area outside the barn in which visitors put on their ‘off-farm’ clothing when entering the barn. All of these measures would be economical.

CHRONIC ENZOOTIC PNEUMONIA OF SHEEP (CHRONIC NON-PROGRESSIVE PNEUMONIA, SUMMER PNEUMONIA, PROLIFERATIVE EXUDATIVE PNEUMONIA)

**Synopsis**

**Etiology** Unknown, multifactorial

**Epidemiology** Affects sheep under 12 months of age. Seasonal occurrence, summer and autumn in southern hemisphere. Common disease affecting most flocks but severity varies between farms

**Clinical findings** Insidious onset. Coughing, nasal discharge and uneven weight gain

**Lesions** Consolidation of anteroventral lobes of lung. Pleuritis

**Diagnostic confirmation** Postmortem lesions

**Treatment** Antimicrobials for severely affected individual sheep

Control No effective control procedure established

Enzootic pneumonia is defined here as the common, lowly pathogenic disease of sheep, particularly lambs, which is common in all sheep populations. The disease is recognized by different names in different areas of the world. It can be differentiated from the acute fibrinous pneumonia and pleurisy associated with Mannheimia (Pasteurella) haemolytica, which is often called enzootic pneumonia in the British literature, and from the chronic progressive pneumonia, maedi and jaagsiekte.

**ETIOLOGY**

Although the disease is well-known, its cause is not well defined. This is partly due to its non-fatal character, which leads to incomplete examination of early cases; most of those submitted for examination or necropsy are distorted by mechanisms in order to initiate lesions; several different strains may be isolated that requires compromised lung defense (PI -3) virus, adenovirus, a respiratory syncytial virus, and reovirus have been nominated as causes.

**Mycoplasma ovipneumoniae**

M. ovipneumoniae is considered to be important in the disease complex and may be the initiating cause.1-4 It is commonly isolated in large numbers from the lungs of affected sheep, but can also be isolated from the nasal cavity of some normal sheep and less occasionally from normal lung. Experimental challenge with pure cultures of the organism produces minimal lesions, but aerosol or intrabronchial challenge with homogenates of affected lung that contain the organism produces proliferative interstitial and lymphoid pneumonic lesions indistinguishable from the natural disease.3,5 M. ovipneumoniae is a facultative pathogen that requires compromised lung defense mechanisms in order to initiate lesions; infection with this organism subsequently predisposes the lung to secondary infection with organisms such as Paste. haemolytica.1,3 There is considerable heterogeneity in M. ovipneumoniae and several different strains may be isolated from a pneumonic lung.5 Differences between strains in pathogenicity are not determined. Other mycoplasma, including M. mycoides subsp. mycoides, M. mycoides subsp. capri, M. putrificans, and M. arginini may be associated with chronic enzootic pneumonia in tropical zones.6

**B. parapertussis**

B. parapertussis is a common isolate from the nasal cavities and lungs of sheep with chronic enzootic pneumonia and is also believed to have an initiating role in the disease.7 It produces a cytotoxin that damages ciliated epithelium in the trachea and experimental challenge of colostrom-deprived lambs produces mild pulmonary lesions similar to those seen early in the natural disease. B. parapertussis also can predispose pneumonic pasteurellosis.8

**Parainfluenza-3 (PI-3) virus**

PI-3 is a cause of a mild undifferentiated pneumonia in sheep, and surveys around the world have shown that it is a widespread infection.2,4 The disease is clinically mild and marked by the presence of interstitial pneumonia. Antibodies to PI-3 are present in lambs soon after birth, but the half-life is short and lambs are susceptible by the time they are weaned and mixed with other lambs, which is when clinical disease often occurs. In the experimentally produced disease in lambs there is a slight seromucosal nasal discharge, coughing, increased sensitivity to tracheal compression, and fever of 40-41°C (104-105°F). At necropsy there is obvious hyperemia of the upper respiratory mucosa, including the trachea, the bronchial lymph nodes are enlarged, and there are small foci of catarrhal inflammation of pulmonary parenchyma of the apical and cardiac lobes.9 However, challenge of lambs at 2 weeks of age with this...
virus and *Mann. haemolytica*, while producing disease, did not result in prolonged disease lasting to slaughter, and it was concluded that these agents, without other factors, were not the cause of enzootic pneumonia. This conclusion is supported by the results of vaccine trials with PI-3 against enzootic pneumonia.

**Bovine respiratory syncytial virus (BRSV)**

BRSV has resulted in pneumonia following experimental challenge of sheep and is evidenced clinically by fever and hyperpnea, and pathologically by multifocal pulmonary consolidation and necrosis of epithelial cells. There is little evidence for BRSV as a cause of significant respiratory disease in sheep.

**Other agents**

*Adenovirus* and a type-3 *reovirus* have been used experimentally to produce pneumatic lesions, and a vaccine has been produced to protect lambs against the adenovirus infection. Similarly, sheep herpesvirus, *caprine herpesvirus-1*, will produce an interstitial pneumonia in experimentally challenged SPF lambs, but there is no evidence of a causal association with chronic enzootic pneumonia. Autoantibodies to upper respiratory cilia have been detected in sheep colonized with *M. ovipneumoniae* and it is suggested that they contribute to the pathogenesis of coughing in this disease.

**EPIDEMIOLOGY**

**Occurrence**

Enzootic pneumonia affects animals up to 12 months but may commence as early as 6 weeks of age. The disease can occur in both lambs at pasture and housed lambs. In many affected flocks, 80% of 4-5-month-old lambs have clinical signs and lesions, and the disease is credited with causing a significant depression in growth rate after weaning in lamb flocks with a high prevalence. This has been confirmed in controlled studies on the effect of the experimentally produced disease on weight gain in housed and pasture-fed lambs.

Enzootic pneumonia has a seasonal pattern which differs according to locality and management. In Australia and New Zealand, the period of peak prevalence is in the late summer and autumn. In a longitudinal slaughter study of lambs in New Zealand the prevalence of pneumonia was found to increase from early summer to early autumn with an overall prevalence of pneumonia of 42%. There were significant differences in prevalence between different regions of the country. Factors such as co-mingling sheep from different sources and environmental stress can precipitate clinical disease.

**Environmental risk factors**

In Australia and New Zealand, clinical outbreaks of enzootic pneumonia in lambs aged 5-8 months are often associated with heat stress, frequent yarding after weaning, use of plunge or shower dips, and transport or mustering of sheep in hot dry conditions. Cases commence within 1-3 weeks after transport. In contrast in the United Kingdom and Europe this disease occurs primarily in the late winter and early spring and in the Northern hemisphere the disease is commonly associated with problems in the housing environment. In Ireland, an association has been made between the occurrence of lesions at slaughter and the extent of rain and windchill experienced by the sheep in the 2 months prior to slaughter.

**Economic importance**

Death loss from this disease is minor but economic loss is considerable and includes reduced growth rate, prolonged periods on the farm before reaching slaughter weight, the drug and labor costs associated with treatment, slaughterhouse wastage, and downgrading of carcasses with pleural adhesions and an effect on carcass quality. The situation is similar to that with enzootic pneumonia of pigs.

**CLINICAL FINDINGS**

The disease is insidious in onset and persists in a group of lambs for 4-7 months. The disease is mild in its clinical manifestations, and the primary signs are poor nasal discharge, coughing, an increased respiratory rate, and respiratory distress with exercise. Increased intensity and a higher pitch of breath sounds are heard on auscultation over the region of the bronchial hilus, and sounds of fluid in the airways are heard in some cases at rest but can usually be elicited by inducing the lamb to cough. There may be periods of fever.

There is a relationship between the proportion of the lung affected with pneumonia and average daily gain and in one study weight gain was reduced by 50% when greater than 20% of the lung was affected. The weight loss is most apparent clinically soon after the disease commences.

**NECROPSY FINDINGS**

At postmortem there are clearly demarcated areas of consolidation in the anteriocentral lobes and there may be pleuritis with pleural adhesions. The diagnosis is on gross lesions and the presence of typical lesions on histological examination.

**TREATMENT AND CONTROL**

Treatment is not usually undertaken unless there is secondary infection to produce acute respiratory disease. Control is based on the avoidance of stress factors that can exacerbate existing infection.

**REFERENCES**

**OVIDINE PROGRESSIVE PNEUMONIA (MAEDI, MAEDI­VISNA)**

Ovine progressive pneumonia and maedi are North American and European terms for slow virus diseases of sheep in which a chronic progressive pneumonia is a major manifestation. The name maedi is derived from the Icelandic term for dyspnea. Maedi-visna virus can also produce visna which is a disease of the nervous system and is discussed elsewhere under that heading. Additional manifestations of infection are arthritis, indurative mastitis, and ill-thrift. These diseases have a close relationship with caprine arthritis encephalitis. La bouhite and Graff-Reinert disease are local names for maedi in France and South Africa, respectively. In the United States it was originally described as Montana progressive pneumonia, and in Holland as zwoegersiekte.
ETIOLOGY

Maedi-visna virus and ovine progressive pneumonia virus are ovine lentiviruses; non-oncogenic ovine retroviruses which constitute a species of the lentivirus genus. They induce a persistent infection in sheep that may cause lymphoproliferative changes in the lung, mammary tissues, brain, and joints. There is a high degree of relatedness with the lentivirus associated with caprine arthritis-encephalitis, and the ovine and caprine lentiviruses share nucleotide homology and serological properties.1,2

Although they belong to a single virus species, isolates obtained from naturally infected sheep are genetically heterogeneous, antigenic drift is common, and antigenic variation of the surface protein facilitates the persistence of the virus in the host. There is evidence for variation in pathogenic potential between isolates.

There is some evidence that the North American strains of ovine lentivirus may have originated from cross-species transmission of caprine arthritis-encephalitis virus rather than from maedi lentivirus,3 but the similarity in clinical manifestation of maedi and ovine progressive pneumonia permits the discussion of these diseases as a single entity.

EPIDEMIOLOGY

Occurrence

The earliest reports of the disease were from South Africa and the United States, but it now occurs in all major sheep-producing countries with the exception of Australia, New Zealand, Iceland, and Finland. The disease was present in Iceland but was eradicated in 1965. Maedi-virus was introduced into Iceland in 1933 by the importation of infected sheep, and because of breed susceptibility of the local sheep and management practices it developed into a problem of major national significance. In individual flocks the annual mortality was often 15–30% and in these circumstances sheep farming was not economically feasible. Approximately 105,000 sheep are believed to have died of the disease and 650,000 sheep had to be slaughtered in order to eradicate it from the country.4

The international movement of sheep has facilitated the spread of the disease and it is believed to have been introduced into Denmark, Norway, Sweden, and Great Britain since the 1970s through the importation of infected sheep. No other country has experienced the severity of disease that occurred in Iceland.

Host range

Sheep and goats are the only species known to be susceptible and infection cannot be established by experimental challenge in cattle, deer, pigs, dogs, horses, chickens, mice, and rats.5 Rabbits are susceptible, but infection is limited to the acute stage prior to the production of antibody, and chronic infection does not occur as it does in sheep and goats.5 A serological survey of wildlife in the United States has shown no evidence of infection in bighorn sheep, elk, white tail deer, or antelope.5 All breeds of sheep appear to be susceptible to infection, but there may be differences in breed susceptibility based on breed differences in seroprevalence in flocks with more than one breed of sheep.6,7 Differences in breed susceptibility are not consistent and it is possible that in any one flock they reflect differences in the susceptibility of family lines within the breed.7 Apparent differences in breed susceptibility in surveys could also be a reflection of management differences between flocks and regions.7,8

Prevalence

The prevalence of infection varies between farms, breeds, and countries. In the United States, true prevalence is not known, but a seroprevalence of 26% is recorded in samples voluntarily submitted from sheep in 29 States, and 48% of flocks had one or more seropositive sheep. An earlier study found 1–68% reactors in culled ewes from different States. Infection appears more common in western States.9 A random nationwide survey in Canada10 found 19% of sheep over 1 year of age with antibodies; 63% of flocks were infected, and the mean flock prevalence was 12%; similar prevalence rates are recorded for the province of Ontario.11 The disease does not have significant national occurrence in countries such as the United Kingdom where infection has been introduced relatively recently, but there is concern that the prevalence may be increasing.12,13 Prevalence rates vary markedly between countries and between flocks in the same country.4,8,11,14

There is considerable variation in the prevalence of seropositive sheep between flocks. Rates of seropositivity increase with age, and flock seroprevalence is influenced by the average age of the flock.

Flock seroprevalence also has been positively associated with the use of foster ewes, allowing lambs older than 1 day to have contact with other lambing ewes, flock size, close contact during confinement for lambing, stocking density on pasture, and the length of time that the flock has been in existence.9,11 Rates of seropositivity are much higher in flocks that also are infected with pulmonary adenomatosis than in those which are not.15

Transmission

The disease is spread by the respiratory route, by ingestion of infected milk and by in utero infection. The relative importance of these routes appears to vary with the flock and its management, but lateral transmission is important in all.

Lambs may contract the infection at birth, or shortly following, from contact with infected ewes or from ingestion of infected colostrum and milk. Mononuclear cells in the colostrum and milk of infected ewes are infected with virus and virus from these cells may pass through the intestinal wall to infect the lamb.16 Lambs born to seropositive ewes have a significantly greater risk for infection than those from seronegative ewes, and lambs born to ewes that have been infected for a long time are at greater risk for infection. The chance of transmission to lambs from infected ewes increases with the period of contact but can occur within the first 10 hours of life.7,11

Lateral transmission can also occur in older sheep. Lateral transmission appeared an important method of transmission of the disease in Iceland and the Basque area and has been a significant component of the spread of the virus in flocks in the United Kingdom since its initial introduction.12,13,17 In some flocks, the spread of infection can be rapid and the majority of the flock can seroconvert within a few years of the introduction of infected sheep.12,18

Infection can be transmitted in utero but the relative importance of this route in the spread of the disease in flocks is debated.13,39 Virus is also shed in the semen of infected rams that have leukospermia.8
The spread of infection is frequently very rapid in flocks that are concurrently infected with the retrovirus causing pulmonary adenomatosis. Macrophages are numerous in the lungs of sheep affected with pulmonary adenomatosis, and these cells will be infected with ovine progressive pneumonia virus where there is a dual infection. The copious lung fluid produced by sheep with pulmonary adenomatosis contains maedi–visna virus in dual-infected sheep and is believed to increase the risk for lateral transmission.

**Economic importance**

The economic importance of the disease rests with losses associated with decreased longevity, mortality with clinical disease, decreased value of culled animals and possible effects of subclinical infection on productivity.

**Clinical disease** occurs in sheep 2 years old or older, usually in sheep 3 to 4 years of age and is more likely to appear when the infection prevalence exceeds 50%. The case fatality rate is 100%. Whereas infection is common in many flocks, the occurrence of clinical disease is commonly rare as most infections are subclinical. High mortality rates occurred in infected flocks in Iceland and in some flocks in the USA, but this is the exception and in most infected flocks clinical disease is rare. Despite the high serological prevalence in areas of Canada, ovine progressive pneumonia is not a common diagnosis in the region's diagnostic laboratories.

It is possible that the major economic loss associated with infection with these viruses rests with the effects of subclinical infection on productivity of infected flocks. Subclinical infection of breeding ewes in some flocks has been associated with a reduction in conception rate, as well as lowered birth weights in some flocks and/or reduced growth rates in their lambs. The reduction in growth rate of the lamb has a significant association with changes in the udder of the ewe and probably results from lowered milk intake. This may be reflected in depression of growth rate only in lambs from older parity ewes. In other flocks, there has been no evidence of effect on the birth weight or growth rate of lambs born of infected ewes. Subclinical infection has no effect on mature ewe body weight or greasy fleece weight.

**PATHOGENESIS**

The virus infects cells of the monocyte-macrophage lineage and attaches to cells by the binding of its envelope glycoprotein to specific receptors on the cell surface. The virus replicates its RNA genome via a DNA intermediate provirus which is integrated into the chromosomal DNA of infected cells. With initial infection there is virus replication; this is followed by an immune response that restricts viral replication but fails to eliminate the virus completely. The immune response occurs between 2 and 8 weeks after infection, with antibody to different viral antigens emerging at different times during this period. Serological latency, with some sheep not developing an antibody response until several months after infection, is recorded.

Replication is restricted and does not proceed beyond the synthesis of provirus in most infected cells. The principal virus replication is in the macrophage, and pulmonary secretions and milk containing infected macrophages are the main source of virus for natural transmission. Diseases such as pulmonary adenomatosis, which increases the number of macrophages in lung secretions, will facilitate transmission of ovine progressive pneumonia virus.

There is persistence and replication of virus in the presence of viral-specific immune responses, with the development of immune-mediated lesions in various organ systems. Persistent production of viral antigen results in lymphocytic hyperplasia. The infected macrophages in the various tissues are surrounded by an inflammatory response creating a focus of mononuclear cell aggregation. The lungs, mammary gland, brain, joints, lymph nodes, and blood vessels are affected by the maedi–visna/ovine progressive pneumonia viruses and, whereas any or all of these organs can be affected in a single sheep, breed and virus differences often lead to a predominance of a single syndrome in a flock.

In the lung there is a gradual development of an interstitial pneumonia without any evidence of healing or shrinkage of tissue, so that the lungs continue to increase in size and weight. The alveolar spaces are gradually filled so that anoxia develops. The pathological lesions develop very slowly during the preclinical and clinical stages of the disease, so that they are very widespread and uncompensatable when clinical signs appear. In the central nervous system there is infiltration of the meninges and white matter with lymphocytes. The demyelination that occurs in visna is believed to result from the direct effect of the virus on oligodendrocytes and astrocytes as well as being the result of an inflammatory response provoked by the presence of viral antigen in these cells. Similar infiltrations occur in the udder. Lymphoid follicles are found in the alveolar parenchyma, often with atrophy of the alveolar tissue. Numerous lymphocytic follicles also occur around the lactiferous ducts, some of which may be occluded by lymphocytic aggregates protruding into their lumens.

**CLINICAL FINDINGS**

There is a long incubation period and clinical disease, if it occurs, does not develop before 2 years of age. Most clinical sheep are older than 3 years. The clinical signs develop insidiously, progress slowly, and there is a long clinical course. The earliest signs are usually listlessness and loss of body condition which progresses to emaciation. The presenting syndrome can be one of an increased cull rate of ewes in poor condition. Signs of respiratory involvement are not evident in the initial stages of the disease, but there is exercise intolerance and affected sheep will fall back behind the flock when the flock is moved. Dyspnea with an increase in respiratory rate and flaring of the nostrils, or open mouth breathing, develops later. There is no evidence of excess fluid in the lungs. The respiratory rate is increased to 80–120/min at rest. There may be coughing and some nasal discharge, but in most instances this occurs in sheep with secondary bacterial pneumonia. There may be inflammation of the third eyelid. The body temperature is in the high normal range. Clinical illness lasts for 3–10 months and the disease is always fatal. Clinically affected sheep are more prone to diseases such as pregnancy toxaemia. In some sheep, clinical respiratory disease is minimal and the major manifestation is wasting and the thin ewe syndrome.

The involvement and induration of the mammary glands is also insidious in onset, and ewes are usually in their third or later lactation by the time the disease fully manifests, although histological change is evident earlier. In early stages it is more easily detected at the time of drying off. In advanced cases the udder is enlarged and uniformly very firm, but the teats are limp and there is very little milk in the teat cistern. The milk is normal in appearance. Mammary involvement may occur, along with signs of respiratory infection, or affected ewes may show no other clinical abnormality. It is called colloquially hard bag or hard udder. The lambs of ewes with less severe involvement may show growth retardation.

Arthritis is occasionally seen in naturally infected sheep but this manifestation appears restricted to the United States. It occurs in sheep from 1 to 6 years of age. The carpal joints are most commonly involved and show obvious
swelling. Affected sheep become lame and emaciated.

**CLINICAL PATHOLOGY**

There is a progressive, moderate hypochromic anemia, with hemoglobin levels falling from 12–14 g/dL down to 7–8 g/dL and some depression of the red cell count. There is a tendency to leukocytosis, and in experimental cases this is observed to be quite marked in the period between exposure and the onset of clinical disease, but the count returns to normal when signs appear. There is also hypergammaglobulinemia. Lymphocytes and neutrophils in bronchoalveolar lavage fluid are increased in number, with an increase in CD8 cells and decrease in CD4 cells and an inversion of the CD4/CD8 ratio.

In clinical cases diagnosis is by the presence of the appropriate clinical syndrome, supported by the presence of a positive serological test for the virus. A positive serological test, by itself, has limited value as an aid to diagnosis of disease in the individual sheep, as there is a high prevalence of seropositivity in many flocks, especially in the older animals. A positive test does indicate that the animal is infected but does not indicate that signs or lesions are attributable to infection with the virus. Thus, for example, a positive serological test in a wasting ewe could only be considered as supportive for a diagnosis of this disease as the cause of the chronic wasting.

**Flock status** with respect to the presence or absence of infection and the determination of the infection status of an individual sheep currently relies on serological testing.

**Antigen detection.** Antigen can be detected by PCR but this detection method for this disease is not commonly available. PCR is a sensitive method for detection of small amounts of viral nucleic acid but its expense is likely to preclude its use in routine diagnosis. It has been used to detect antigen in the third eyelid of infected sheep.

**Serological tests.** **Flock status** with respect to the presence or absence of infection and the determination of the infection status of an individual sheep currently relies on serological testing. Agar gel immunodiffusion (AGID) tests, and ELISA tests are used in most countries. The AGID test is easy to perform and is inexpensive, and for these reasons is probably the most common test in use for routine diagnostic testing. The AGID test with the appropriate antigen is considered to have high specificity, but may lack in sensitivity. Indirect ELISA and competitive ELISA tests may have better sensitivity, depending on the antigen used. The slow development of antibody following infection must be considered in the interpretation of a negative test. An analysis of currently available test systems showed high specificity but sensitivities that were inadequate for diagnosis of infection in individual animals – varying from 64% to 97%. A competitive-inhibition ELISA for the detection of antibodies to the surface envelope antigens has reported high sensitivity and specificity.

The value of serological testing with current methodologies rests primarily with the establishment of the infection status of the flock. A negative test in an individual sheep could mean that the sheep is free of infection, but can also occur in an infected animal that has not yet responded to infection.

**NECROPSY FINDINGS**

Lesions may be present in the lungs and associated lymph nodes, brain, joints, mammary gland and blood vessels, but gross lesions in most sheep are confined to the lungs and, in some cases, the mammary glands. In advanced cases, the lungs are larger and two to four times as heavy as normal lungs. They collapse much less than normal when the chest is opened, and are gray-blue to gray-yellow in color. There is a diffuse thickening of the entire bulk of both lungs, and the abnormal color and consistency are generalized and unvarying in all lobes. Enlargement of the bronchial and mediastinal lymph nodes is constant. Histopathological changes are characteristic of a chronic interstitial pneumonia, with proliferation of lymphoid tissue and the presence of numerous lymphoid follicles. There is infiltration of lymphocytes and macrophages in the interalveolar septa, which are thickened, and the bulk of the alveolar space is replaced by the thickened alveolar walls. Larger airways are unaffected. There is a complete absence of healing, suggesting that the disease is a progressive one and never reaches a healing stage. A vasculitis is often a significant lesion.

There are frequently associated lesions of arthritis, encephalitis, and mastitis. The mastitic lesion comprises an interstitial accumulation of lymphocytes and the presence of periductal lymphoid nodules with atrophy of alveolar tissue. Culture of the virus is difficult, and confirmation of the diagnosis is often limited to the presence of characteristic microscopic lesions, preferably supported by a positive serologic titer to the virus. Nucleic acid probe techniques discussed above are not yet widely available.

**Samples for confirmation of diagnosis**

- **Virology** – lung, mammary gland, synovial membrane, brain (ISO)
- **Serology** – heart blood serum (AGID, ELISA)
- **Histology** – formalin-fixed lung, bronchial lymph node, mammary gland, synovial membrane, half of midsagittally-sectioned brain (LM).

**DIFFERENTIAL DIAGNOSIS**

There are several chronic pneumonias requiring differentiation from maedi:

- Jaagsiekte
- Parasitic pneumonia
- Chronic suppurative pneumonia
- Caseous lymphadenitis
- Post-dipping pneumonia
- Enzootic pneumonia (pp. 1336–1343)
- Melioidosis (pp. 1082–1083)

Chronic wasting conditions:

- Johne’s disease (pp. 1017–1044)
- Caseous lymphadenitis.

**TREATMENT**

No treatment has been successful.

**CONTROL**

In the past, the only control attempted has been eradication of the disease by complete destruction of all sheep in the area and subsequently restocking. However, it is possible to greatly reduce the prevalence by either of two methods.

**Segregated rearing**

This requires a management system of separating the lambs from the ewes at birth, giving them no colostrum, or bovine colostrum, and rearing them on milk replacer quite separately from other sheep. This method is effective in establishing an infection-free flock and is of particular value where there is a requirement to retain genetic lines in the eradication procedure. However, it is very labor-intensive and expensive, and there is no cash flow unless the infected sheep are maintained in production pending the establishment of a mature infection-free flock. This can create a considerable potential for re-infection of the artificially reared flock.

**Test and cull**

This involves the detection and culling of seropositive animals and is the preferred method where lateral transmission is the dominant mode of transmission in the flock. All sheep (and goats) on the farm are serologically tested annually or twice a year, and seropositive animals and their progeny of less than 1 year of age are culled. Ideally they should be slaughtered.
but this may not be economically feasible, in which case they must be kept separate from the seronegative sheep. The seronegative flock must subsequently be kept isolated from infected sheep, as well as people and equipment in contact with the seropositive animals. Testing is continued semiannually or annually until there are at least two consecutive negative tests. The offspring of older seronegative ewes are kept for replacements.

Future flock introductions with both methods should be from a seronegative flock.

**Other control procedures**
Control procedures that attempt to limit or delay the spread of infection, and consequently the occurrence of clinical disease within an infected flock, have limited success. Shed lambing and close lambing is thought to be very conducive to infection. The identification of these flocks. In flocks that have a high incidence of inter-farm movement and outdoor housing may limit the spread of the disease. With regard to the clinical disease, the determination of the age of onset of clinical disease and the establishment of a culling policy based on this information can reduce the economic impact of the disease.

In countries where the disease is enzootic, there is often a great deal of movement of animals between farms, especially of rams, and in some management systems of replacement ewes. Flock introductions should be from seronegative flocks where possible. In several countries, breed societies, or other bodies, have established certification programs for flocks free of this infection. In the absence of such programs, severe restriction of inter-farm movement and outdoor housing may limit the spread of the disease.

The fact that some sheep in infected flocks retain freedom from infection in the face of continual exposure to infection suggests that there is a genetic resistance to infection. The identification of these determinants may prove to be the future method for the control of this disease. There is currently no effective vaccine.  

**Flock biosecurity**
Once infection is introduced to a flock it is difficult and expensive to eradicate and all efforts should be directed to prevent its introduction. The specificity and sensitivity of most currently available serological tests are inadequate to determine the infection status of an individual and the results of flock tests of a potential source of infection should be used coupled with an examination of postmortem records in the potential source flock, if available. Rams and replacement ewes should be acquired from accredited free flocks in countries where these are registered. The sheep should be transported directly from the source farm rather than through a market.

**REVIEW LITERATURE**

**REFERENCES**
the exception of Australia and New Zealand. Until recently there has been no practical method to detect infected sheep and estimates of the prevalence of jaagsiekte are largely based on clinical or postmortem observations. The prevalence of the disease appears to vary depending upon the breed of sheep and the type of flock management. In most endemically infected flocks annual losses attributable to jaagsiekte are between 2% and 10%, although the tumor is present in a much higher proportion of the flock and infection without lesions is also common. Annual mortality can be higher in flocks where the infection has recently been introduced and before the disease becomes endemic. PCR analysis of peripheral blood leukocytes of sheep in infected flocks show significantly higher rates of non-clinical infection.

**Prevalence** varies between countries and there can be **areas of high prevalence** within countries; in Britain, the Borders and the east coast of Scotland, and East Anglia in England, appear to be foci of infection from which other outbreaks arise. The prevalence may be higher than generally recognized and, in a biased sample, histological evidence of jaagsiekte was detected in 25% of cases of pneumonia in sheep submitted to a diagnostic laboratory in Scotland over a 6-year period. The disease is also a significant cause of mortality in adult sheep in South Africa and Peru, but is a minor disease in the United States and Canada.

The disease occurred in epizootic proportions in Iceland during the same period of time as the maedi-visna epizootic, but has been eradicated by a rigorous slaughter policy.

**Animal and environmental risk factors**

**Mature sheep**, 2 to 4 years of age are most commonly affected but the disease can occur in younger animals. There are reports of the occurrence of jaagsiekte in goats at very low prevalence rates in India and Greece, and the disease has been experimentally transmitted to goat kids. The lesions produced were small and circumscribed, and **goats have low susceptibility** to infection.

Jaagsiekte has a prolonged clinical course and is **uniformly fatal**. In some reports there is a greater prevalence of onset of clinical disease in the winter months but in others there is no seasonal variation in clinical onset. Ewes may show a sudden onset of clinical disease in late Pregnancy.

The **incubation period** in natural cases is 1–3 years, but may be as short as 5–12 months after experimental transmission. Clinical disease is rare in sheep younger than 2 years and is most common at 3–4 years of age. Very rarely, cases occur in lambs 3–6 months old and disease can be reproduced in lambs of this age by challenge of very young lambs. A genetic or familial susceptibility to the disease is suspected.

Because of the method of spread, the disease is likely to assume more importance in systems of sheep husbandry where there are significant periods of close contact, as, for example, occurs with intensified lamb-rearing systems. Close housing during the winter is a potent predisposing cause and probably accounted for the occurrence of the disease in epizootic form in Iceland. However, the disease occurs commonly in range sheep in other countries. Sheep that have a combined infection with jaagsiekte and the maedi-visna lentivirus have an increased ability to transmit maedi-visna infection, and flocks with the combined infection can suffer high losses from pneumatic disease.

**Transmission**

Experimental transmission has been effected by pulmonary or IV injection, or by intratracheal inoculation of infected lung material. The incubation period of the experimental disease in young lambs is much shorter than that in mature sheep. The disease has also transmitted by inhalation of infected droplets when sheep are kept in close contact, and it is assumed that the normal mode of transmission is by droplet infection from respiratory secretions, which are copious in sheep with clinical disease. A longitudinal study of the natural transmission showed that infection established readily and rapidly in young lambs and also horizontally in adult sheep, but that the majority of infected sheep did not show clinical disease during their commercial life span.

**PATHOGENESIS**

The virus replicates in the **type II pneumocytes** in the alveolus. Type II pneumocytes and Clara cells in the terminal brochiolae are transformed, and their growth produces intra-alveolar and intrabroncholar polypoid ingrowths. These cells are surfactant-producing secretory cells and there is also copious production of fluid. The excessive surfactant-like protein produced in the tumor provides a stimulus for the accumulation of macrophages seen in association with this disease. The adenomatous ingrowths of alveolar epitheliums encroach gradually upon alveolar air space so that anoxic anoxia occurs. The lesions produced by experimental inoculation are identical with those of the naturally occurring disease.

**CLINICAL FINDINGS**

Affected sheep are afebrile and show progressive respiratory distress with loss of weight. Clinical signs are not evident until a significant proportion of the lung is compromised by the tumor. Occasional coughing and some panting after exercise are the earliest signs but coughing is not a prominent sign in this disease unless there is concurrent parasitic pneumonia. Emaciation, dyspnea, lacrimation and a profuse watery discharge from the nose follow. Death occurs 6 weeks to 4 months later. A diagnostic test, colloquially known as the wheelbarrow test, in this disease is to hold the sheep up by the hind legs in affected animals a quantity of watery mucus (up to about 200 mL) runs from the nostrils. Moist crackles are audible over the affected lung areas and may be heard at a distance, so that a group of affected animals are said to produce a sound like slowly boiling porridge. There is no elevation of body temperature unless there is secondary infection, and the appetite is normal. Advanced cases may have cor pulmonale. Pasteurellosis (Mannheimia haemolytica) is a common complication and often the cause of death.

**CLINICAL PATHOLOGY**

No immune reaction can be detected in affected animals and there is no serological test. Sheep in advanced stages of the disease may show neutrophilia and lymphocytopenia. The pulmonary fluid contains round or spherical clusters of epithelial cells, which have the hyperplastic adenomatous epithelium typical of pulmonary lesions and increased numbers of macrophages. Earlier reports of a consistent elevation in circulating immunoglobulin concentrations have not been substantiated. JSRV can be detected by exogenous JSVR specific PCR in peripheral blood leukocytes.

**NECROPSY FINDINGS**

Lesions are usually restricted to the thoracic cavity. As in maedi, the lungs are grossly increased in size and in weight (up to three times normal). There are extensive areas of neoplastic tissue, particularly of the anterioventral regions of one or both lungs, with smaller lesions in the diaphragmatic lobes. The affected areas are solid and slightly raised above the adjacent normal lung. This, with the excess frothy fluid in the bronchi, is characteristic. The bronchial and mediastinal lymph nodes are enlarged and hyperplastic, and occasionally contain small metastases. Pneumonic pasteurellosis is a frequent complication, and secondary pulmonary abscesses and pleurisy may develop. Histologically, the alveolus is lined by cuboidal and columnar epithelial
cells that form characteristic adenomatous ingrowths of alveolar epithelium into the alveolar spaces.

Samples for confirmation of diagnosis
- Histology - formalin-fixed lung, bronchial lymph node (LM).

Differential diagnosis
- Chronic pneumonia
- Enzootic pneumonia
- Mycoplasma pneumonia
- Caseous lymphadenitis
- Post-dipping pneumonia
- Melioidosis.

Diagnosis
Reduce the prevalence of disease by sampling for confirmation of infection.

In Iceland, where the disease assumed epizootic proportions, eradication was effected by complete slaughter of all sheep in the affected areas. In areas where the prevalence is lower, the disease can be satisfactorily controlled, but not eradicated, by slaughter of the clinically affected sheep. There is evidence that the disease is spreading in sheep populations in some countries, and flocks that are free of disease should attempt to obtain replacement sheep from flocks that are free of jaagsiekte. Infected flocks can reduce the prevalence of disease by culling sheep at the onset of clinical signs, and also culling the progeny of affected ewes. There is no detectable immune response in affected animals. At postmortem, the tumor masses are in the ethmoid turbinates, with metastasis to regional lymph nodes in some cases. The tumors may be unilateral or bilateral and are gray or pink in color with a granular surface. The tumors originate in the serous glands of the turbinates and have the histological features of adenocarcinoma. The disease can be transmitted experimentally in both goats and sheep with challenge of young kids resulting in disease at 12–16 months of age.5,6

Viral diseases characterized by nervous signs

EASTERN AND WESTERN VIRAL ENCEPHALOMYELITIS OF HORSES

Synopsis
Etiology Eastern encephalitis and Western encephalitis viruses
Epidemiology Disease limited to the Americas. Arthropod, usually mosquito, borne virus. Mammals, including horses, are accidental hosts. Horse is dead-end host for WEE and WEE. Case fatality rate 5–70%. WEE and EEE occur as sporadic cases and as outbreaks
Clinical signs Fever, muscle fasciculation, severe depression, head pressing, incoordination, recumbency, opisthotonos and paddling, and death
Clinical pathology Leukopenia
Lesions Non-suppurative encephalomyelitis
Diagnostic confirmation Virus isolation and identification. Identification of virus antigen by indirect immunofluorescence. Serological confirmation of exposure, preferably demonstrating an increase in hemagglutination inhibition, virus neutralization, or complement fixation titer
Treatment No specific treatment. Supportive care
Control Vaccination with formalin-inactivated vaccines (EEE, WEE) insect control
ETIOLOGY
Equineencephalomyelitis is associated with one of the two immunologically distinct arthropod borne alphaviruses (family Togaviridae): **Eastern equine encephalomyelitis virus (EEE)**, **Western equine encephalomyelitis virus (WEE)**.

- There is one EEE virus strain, but two antigenic variants of it: North American and South American.
- WEE likely arose as a recombinant of EEE and Sindbis virus. There are strains of WEE from Argentinian, Brazil, and South Dakota that differ antigenically and there are 4 major lineages of WEE in California whose geographical distributions overlap.

All the viruses are extremely fragile and disappear from infected tissues within a few hours of death. **WEE** is the least virulent of these viruses in horses and humans.

EPIDEMIOLOGY
These encephalitis viruses cause disease in horses, humans, pigs, and various birds including rats and domestic pheasants.

**Distribution**
Equine Eastern and Western encephalomyelitis viruses are restricted to the Americas. The two viruses have distinct geographical ranges that may overlap: **EEE** is restricted to South America and North America generally east of the Mississippi river whereas **WEE** is found west of the Mississippi river and predominantly in the western United States and Canada, although it also occurs in Florida and South America.

**Viral ecology**
Humans, horses, cattle, pigs, dogs, and rats are accidental hosts of the virus. The EEE and WEE viruses are normally maintained in a host–vector relationship by cycling between mosquitoes, and some other hematophagous insects, and the definitive host. However, there are some important differences in the ecology of the different viruses.

**Western equine encephalomyelitis**
The definitive hosts of endemic WEE are wild birds, which are not clinically affected, and the vectors are the mosquitoes *Culex tarsalis* (in the western United States) and *Culiseta melanura*, an inhabitant of drainage ditches and swamps. However, other mosquitoes, including *Aedes sollicitans* and *A. texans*, can propagate the virus through infection of large shore birds. The Carolina chickadee and yellow-crowned night-heron are the most common avian hosts in the southeastern United States. Horses are usually dead-end hosts, although viremia may be sufficiently severe in some horses to permit infection of mosquitoes. The reservoir of the virus during winter is not known, but may involve the vertical transmission of infection to larvae that survive the winter.

**Epidemics** of EEE have occurred in the provinces of Ontario and Quebec, in virtually all the states of the United States east of the Mississippi River, and in Arkansas, Minnesota, South Dakota, and Texas, in many of the Caribbean Islands, in Guatemala, Mexico, and Panama, and in Argentina, Brazil, Columbia, Ecuador, Guyana, Peru, Suriname, and Venezuela.

**PATHOGENESIS**
Inapparent infection occurs in inland States of the United States, and frequently the source of the infection is undetermined, although *meteorological factors* that allow rapid movement of infected mosquitoes may be important. For instance, in 1972, outbreaks of EEE occurred in Quebec, Canada and in Connecticut, USA that originated with mosquitoes carried on surface winds from Connecticut to Quebec, a distance of 400 km, in 14–16 hours at a speed of 25–30 km/h and a temperature of 15°C.

There may be a continual cycle of EEE virus in mosquitoes and birds in the southeastern US, from where the virus could be distributed by infected mosquitoes on the wind along the Gulf and Atlantic Coasts and up the Mississippi Valley.

**Animal risk factors**
Recovered horses are resistant to infection for at least 2 years, and vaccination confers immunity of variable duration (see under 'Control'). **Unvaccinated horses** are at increased risk of disease – the risk of a vaccinated horse contracting EEE is only 0.14 that of an unvaccinated horse. The disease is more severe, and mortality is higher, in unvaccinated horses than in vaccinated horses. The mortality in young foals from non-immune mares, that are infected with WEE, is always high, often as high as 100%.

**Housing and exposure to mosquitoes** are important risk factors for EEE, and presumably WEE. During an outbreak in 1831, only horses kept at pasture were affected. The use of insect repellants reduces the odds of a horse being infected with EEE to 0.04 that of an unprotected horse. Similarly, keeping horses at pasture near woods increases the risk of disease by almost four times, and the presence of swamp land increases the risk by over two times. Horses kept in areas with high precipitation have an increased risk of the disease, presumably because of the density of mosquitoes in these areas.

**Morbidity and case fatality**
Morbidity varies widely depending upon seasonal conditions and the prevalence of insect vectors; cases may occur sporadically or in the form of severe outbreaks affecting 20% or more of a group. The prevalence of infections, as judged by serological examination, is much higher than the clinical morbidity. The **case fatality rate** differs with the strain of the virus; in infection with the WEE virus it is usually 20–30% and with the EEE it is usually between 40 and 80% and may be as high as 90%.

**Zoonotic implications**
The susceptibility of humans to the causative virus gives the disease great public health importance. Humans can become infected with the EEE virus and the WEE virus.

**PATHOGENESIS**
Inapparent infection is the mildest form of the disease and may be characterized by only a transient fever. A more severe form of the disease is manifested by tachycardia, depression, anorexia, occasional diarrhea, and fever.
are localized particularly in the gray matter of the cerebral cortex, thalamus and hypothalamus, with minor involvement of the medulla and spinal cord. It is this distribution of lesions that is responsible for the characteristic signs of mental derangement, followed at a later stage by paralysis. The early apparent blindness and failure to eat or drink appear to be cortical in origin. True blindness and pharyngeal paralysis occur only in the late stages.

**CLINICAL FINDINGS**

The diseases associated with EEE and WEE viruses are clinically indistinguishable. The incubation period for EEE is 1–3 days and 2–9 days for WEE. Uncomplicated disease usually lasts about 1 week. In the initial viremic stage there is fever, which may be accompanied by anorexia and depression, but the reaction is usually so mild that it goes unobserved. In the experimental disease, the temperature may reach 41°C (106°F) persisting for only 24–48 hours, with signs of neurologic dysfunction appearing at the peak of the fever. Animals that have signs of neurologic disease for more than 24 hours are often not pyrexic.

Initial signs of neurologic disease include hypersensitivity to sound and touch, and in some cases transient periods of excitement and restlessness, with apparent blindness. Horses can have a period of anorexia and colic before onset of signs of neurologic disease. Affected horses may walk blindly into objects or walk in circles and in severe cases can mimic signs of horses with catastrophic intestinal disease. Involuntary muscle movements occur, especially tremor of shoulder and facial muscles and erection of the penis. A stage of severely depressed mentation follows. Affected horses stand with the head hung low; they appear to be asleep and may have a half-chewed mouthful of feed hanging from the lips. At this stage the horse may eat and drink if food is placed in its mouth. The pupillary light reflex is still present. The animal can be aroused, but soon relaxes into a state of somnolence.

A stage of paralysis follows. There is inability to hold up the head, and it is often rested on a solid support. The lower lip is pendulous and the tongue protrudes from the mouth. Unnatural postures are adopted, the horse often standing with the weight balanced on the forelegs or with the legs crossed. Head-pressing or leaning back on a halter are often seen. On walking, there is obvious incoordination, particularly in the hindlegs, and circling is common. Defecation and urination are suppressed and the horse is unable to swallow. Complete paralysis is the terminal stage. The horse goes down, is unable to rise and usually dies within 2–4 days from the first signs of illness. A proportion of affected horses do not develop paralysis and survive, but have persistent neurologic deficits.

**Pigs**

EEE causes an encephalitis and myocarditis of piglets less than 2 weeks of age. The disease is characterized by incoordination, seizures, vomition, weight loss, and paddling. Recovered piglets can have retarded growth.

**CLINICAL PATHOLOGY**

There are no characteristic hematological or biochemical abnormalities. The absence of biochemical indication of liver disease (hyperbilirubinemia, increased activity in serum of liver-specific enzymes such as sorbitol dehydrogenase or gamma glutamyl transferase, absence of hyperammonemia) rules out hepatic encephalopathy.

**Diagnostic confirmation** is achieved by one or more of several means:

- Isolation of virus from an affected animal
- Detection of viral antigen or nucleic acid in an animal with appropriate clinical signs
- Seroconversion or an increase in serum titer of sick or recovered animal

**Virus isolation** provides definitive proof of infection. However, viremia may have resolved by the time nervous signs have developed, and it may be advantageous to sample febrile animals instead of animals showing more advanced signs of the disease. Virus can be cultured in intracranially inoculated suckling mice, weanling mice, guinea pigs, cell culture, newly hatched chicks, or embryonated eggs. Virus isolates can be identified by complement fixation, hemagglutination inhibition, virus neutralization, PCR, IFA, and antigen capture ELISA. Additionally, the ratio of titers of EEE and WEE can be useful in detecting infection by EEE – ratios of >8:1 are highly suggestive of EEE infection.

**NECROPSY FINDINGS**

The brain meninges may appear congested, but there are generally no gross changes. Histological examination of the brain reveals perivascular accumulations of leukocytes and damage to neurons. The gray matter of the forebrain and midbrain are the most severely affected areas. Lesions associated with EEE antigen are also present in myocardium, stomach, intestine, urinary bladder, and spleen. Cell culture and transmission experiments utilizing brain tissue as an inoculum are the traditional means of confirming a diagnosis, and require that the brain be removed within an hour of death. Transmission is by intracerebral inoculation of brain tissue into suckling mice or duck embryo tissue culture. Fluorescent antibody tests have been developed to detect EEE virus in brain tissue. A PCR-based diagnostic test is available for EEE virus. Lesions generally similar to those seen in horses have also been described in a beef cow infected with EEE. The disease in piglets is characterized by disseminated perivascular cuffing, gliosis, focal necrosis of the cerebral cortex, and multifocal myocardial necrosis.

Samples for postmortem confirmation of diagnosis: one half of midsagittally-sectioned brain and liver and spleen should be...
submitted for fluorescent antibody and PCR testing, virus isolation and bioassay
- One half of midsagittally-sectioned brain, fixed in formalin, should be submitted for light microscopic examination.

Note the zoonotic potential of these organisms when handling the carcasses and submitting specimens.

### DIFFERENTIAL DIAGNOSIS

Clinically, the disease has very great similarity to the other viral encephalomyelitides, from which it can often be discriminated by the geographical location of the horse, and to the hepatic encephalopathies and a number of other diseases (see below and in Table 22.1).

West Nile encephalitis - predominantly a myelitis with later development of signs of neurologic disease whereas EEE and WEE have predominant signs of encephalopathy.
- Rabies
- Borna disease - occurs in Europe
- Japanese encephalitis - occurs in Asia
- Various other viral infections that are geographically restricted
- Hepatic encephalopathy, such as that associated with poisoning by *Crotalina*, *Senecio*, and *Amsinckia* spp.; acute serum hepatitis or hepatopathy
- Botulism causes weakness evident as muscle fasciculation, recumbency and dysphagia, but does not cause cerebral signs (irritation, behavioral abnormalities)
- Yellow star thistle poisoning (*Centaura solstitialis*, and poisoning by *Fusarium moniliforme*) can produce similar clinical signs to that of the encephalitides, with the exception of fever.

### TREATMENT

There is no definitive or specific treatment. Supportive treatment may be given with the intention to prevent self-inflicted injury, and maintain hydration and nutritional status.

### CONTROL

Control of viral encephalomyelitis of horses is based on: 6,23,24
- Accurate clinical and laboratory diagnosis of the disease in horses
- Use of sentinel animals to monitor the presence of the virus in the region
- Quarantine of infected horses to stop movement of virus donors
- Insect abatement when deemed necessary
- Vaccination of all horses

### Vaccination

Vaccination of horses is important not only because it minimizes the risk of disease in vaccinated horses but also because of the possibility that for EEE it prevents viremia, subsequent infection of feeding mosquitoes, and propagation of the epidemic.

Formalin-inactivated EEE and WEE virus vaccines are available and are effective although over 50% of horses with EEE had been vaccinated within the previous year. This apparent poor protection can be explained by many horses not developing a detectable change in antibody titer after vaccination with a bivalent vaccine and rapid decreases in antibody titer from a peak value achieved 2-4 weeks after vaccination. 17

Vaccines are available as univalent or bivalent preparations and in combination with other antigens (for instance, tetanus toxoid). Horses should be vaccinated in advance of the anticipated encephalomyelitis season in a given area. Vaccination against both strains of the virus is advisable in areas where the strain has not been identified or where both strains exist. The currently recommended vaccination schedule consists of two doses of the vaccine initially, 10 days apart, followed by annual revaccination using two doses. **Annual revaccination** is currently recommended because the duration of effective immunity beyond 1 year is not known. It is probable that the initial two-dose vaccination lasts for up to 3-4 years. The emphasis in a vaccination program should be on the young horses.

**Colostral antibody** can be detected in the blood of foals from vaccinated dams for up to 6-7 months, after which time it declines rapidly. Foals from vaccinated dams should be vaccinated at 6-8 months of age and revaccinated at 1 year of age. Foals from unvaccinated dams may be vaccinated at 2-3 months of age and again at 1 year of age. Colostral antibodies in the foal will prevent the development of autogenous antibodies, and foals vaccinated at 1 year of age that are 1-year-old or, in high-risk areas, foals from vaccinated mares should be vaccinated at 3, 4, and 6 months of age.

**Experimental DNA vaccines hold promise** for the prevention of WEE.26

### Protection from insects

Housing of horses indoors at night, especially in flyproofed stables, and the use of insect repellents may restrain the spread of the virus. Use of insect repellents decreases the risk of EEE in horses to 0.04 that of unprotected horses.

Widespread spraying of insecticides to reduce the population of the vector insects has been used in the control of VEE, however, such measures are not practical for preventing sporadic cases of EEE or WEE, and the environmental impact of widespread insecticide use should be considered.

Complete eradication of the virus appears to be impossible because of the enzootic nature of the ecology of the virus. The horse being an accidental host for EEE and WEE virus make elimination of the virus impossible with methods currently available.

### Zoonotic aspects of control

**Control of the disease in humans** in areas where the disease may occur is dependent on insect control, and monitoring and surveillance early warning system is necessary to decide whether to take control measures. In areas where WEE occurs, clinical cases of the disease in horses will also assist in predicting potential epidemics of WEE virus infection in the human population. Serological surveys of wildlife may also serve as good indicators of the geographical distribution and seasonality of circulation of these viruses and provide an early warning system prior to the detection of human cases.

### REVIEW LITERATURE

EQUINE ENCEPHALOPATHY

Seven serotypes\(^1\) to 7 of equine encephalitis virus (EEV) infect aequids of southern Africa including Kenya, Botswana and South Africa.\(^1\) The virus is an insect-borne orbivirus that is transmitted by a variety of Culicoides spp.\(^2\) and is closely related to bluetongue and epizootic hemorrhagic disease viruses. It has characteristics in cell culture similar to African Horse Sickness.\(^3\) The virus replicates in midges although the rate differs depending on species of midge and strain of the virus. The genetic and phenotypic stability of strains of the virus are unknown and there exists the potential for emergence, or recognition, of new strains. Variations in pathogenicity are not recognized, perhaps because of incomplete knowledge of this importance of this virus, but might exist. There is independent persistence of virus serotypes in a maintenance cycle based on observation of increased rates of seasonal seroconversion to a specific serotype with ongoing low level of infection by other serotypes.\(^1\) Horses, donkeys, and zebra in southern Africa frequently have antibodies to a group epitope of the virus indicating widespread infection of these Equidae. Seventy percent of 1144 horses, 57% of 518 horses, 49% of 4875 donkeys and up to 88% of zebra in South Africa have antibody to EEV.\(^4\) Elephant seldom have antibodies to EEV.\(^4\)

The virus was originally isolated from a horse with signs of neurologic disease, hence the name. However, the disease associated with infection by EEV is poorly documented and, given the high prevalence of infection, EEV might be falsely incriminated in some situations. Most infections are subclinical based on the high seroprevalence rate and lack of reports of outbreaks of the disease. Clinical signs commonly attributed to EEV infection include fever, lassitude, edema of the lips, acute neurologic disease and enteritis. Abortion has been associated with infection by EEV. Disease associated with EEV has not been recorded in donkeys or zebra.\(^2\) Characteristic abnormalities in serum biochemistry or hematology are not reported. Antibodies to the virus are detected by serum neutralization assays (which are serotype specific) and ELISA, which is not serotype specific. A group specific, indirect sandwich ELISA detects EEV antigen and does not cross react with African Horse Sickness virus, Bluetongue virus, or epizootic hemorrhagic disease virus.\(^6\) Necropsy examination reveals cerebral edema, localized enteritis, degeneration of cardiac myofibers and myocardial fibrosis but whether all these abnormalities are attributable to EEV is unclear.\(^2\) Definitive diagnosis is difficult, if not impossible, at the current time because of the high prevalence of seropositive animals and the ill-defined clinical and necropsy characteristics of the disease. There are no recognized treatment, control or preventive measures. There is no vaccine.

VENEZUELAN VIRAL ENCEPHALOMYELITIS OF HORSES

ETIOLOGY

Venezuelan equine encephalomyelitis is associated with an arthropod borne alphavirus (family togaviridae) Venezuelan equine encephalomyelitis virus (VEE). The VEE complex has one virus, VEE, with six antigenically related subtypes: I, VEE; II, Everglades; III, Mucambo; IV, Pixuna; V, Cabassou; and VI, AG80–663. Within subtype I are at least five variants. Epidemic (pathogenic) VEE in horses is associated with variants IAB (originally identified as distinct variants, A and B and are now considered the same variant) and IC; all other subtypes of 1 (D–F), and other variants of VEE virus, are usually non-pathogenic for horses and are found in sylvatic or enzootic, non-equine cycles. The epidemic variants are exotic to the United States. Outbreaks occurred in Mexico in 1993 and 1996, and in Venezuela and Colombia in autumn 1995.\(^1,2\) The Colombian outbreak affected 90,000 people and killed an estimated 4000 horses.\(^3\) The strain involved in the Colombian outbreak was IC, while that involved in the Mexican outbreaks was a variant of the usually non-pathogenic IE.\(^2\)

The outbreak in Mexico was associated with a variant of VEE that did not cause viremia in horses, although it was capable of causing neurologic disease in this species, and it might have been this attribute that abbreviated the course of the epidemic.\(^3\) There is evidence of continuing enzootic circulation of VEE IE in southern Mexico.\(^4\) The viruses are extremely fragile and disappear from infected tissues within a few hours of death.

EPIDEMIOLOGY

The encephalitis viruses cause disease in horses, humans, pigs, and various birds including ratites and domestic pheasants.\(^5\)

Distribution
Pathogenic or epidemic VEE is found in northern South America, Central America, Mexico and, rarely, in the southern United States.\(^5\) Non-pathogenic, or endemic, strains of VEE are found in South and Central America and in parts of the southern United States.

Viral ecology
VEE exists as both non-pathogenic and pathogenic strains. Non-pathogenic VEE viruses persist in sylvatic cycles in northern South America, Central America and parts of the southern United States, and are important because they are the source of the epizootic strains of the virus that emerge at infrequent intervals.\(^2,6,8\) The enzootic strains also confound the diagnosis of VEE because of the extensive
serological cross-reactivity among endemic and epidemic VEE viruses. However, recent advances in diagnostic techniques may have solved this diagnostic problem. The non-pathogenic viruses are maintained in rodents associated with swamps, and transmitted by mosquitoes of the genus Culex, and perhaps other hematophagous insects. Humans, horses, cattle, pigs, dogs, and ruminants are accidental hosts of the virus. **Epidemics of VEE** occur irregularly, the latest being in northern Columbia in 1993, and Mexico in 1993 and 1996.** The source of virus during outbreaks is infected horses. Horses develop a profound viremia and are amplifying hosts that aid in the spread of the epizootic other domestic species, including cattle, pigs, and goats are not considered to be amplifiers of the virus. During epizootics, all species of mosquitoes that feed on horses, including Aedes, Psorophora and Deinocerites species, are thought to be capable of spreading the infection. Epizootics end as the population of susceptible horses decreases below a critical level, either by death or vaccination. The **reservoir of the virus between outbreaks**, which may be up to 19 years, was unknown until it was demonstrated that epidemic VEE type IAB virus arises by mutation of endemic strains (types ID-F and II-vi), or that type IE (enzootic) mutates into an epizootic form serologically very similar to IE. This mutation of the endemic virus into the epidemic form has occurred on at least three occasions associated with epidemics of VEE. It is likely that pathogenic strains of VEE will continue to emerge in areas where the non-pathogenic strains of the virus are endemic.

**Animal risk factors**

Recovered horses are resistant to infection for at least 2 years, and vaccination confers immunity of variable duration (see under 'Control'). Housing and exposure to mosquitoes are important risk factors for VEE, and presumably VEE.

Morbidity varies widely depending upon seasonal conditions and the prevalence of insect vectors; cases may occur sporadically or in the form of severe outbreaks affecting 20% or more of a group. The prevalence of infections, as judged by serological examination, is much higher than the clinical morbidity. The **case fatality rate** is usually 40–80% and may be as high as 90% with VEE.

**Zoonotic implications**

The susceptibility of humans to the causative virus gives the disease great public health importance. Humans can become infected with sylvatic and epizootic VEE subtypes. A recent outbreak of VEE in Columbia caused 75,000 human cases, 300 fatalities and killed approximately 4000 horses. Human infections generally follow equine infections by approximately 2 weeks. The infection in humans is usually a mild, influenza-like illness in which recovery occurs spontaneously. When clinical encephalitis does occur it is usually in very young, or older, people. Occurrence of the disease in humans can be limited by the use of a vaccine in horses, thus limiting the occurrence of the disease in horses in the area. There is a strong relationship between the mosquito population and the incidence of the disease in horses and in humans. The occurrence of the disease in humans may be predicted by an unusually high activity of virus in mosquitoes. There are usually, but not always, widespread mortalities in horses before the disease occurs in humans. VEE infections have occurred among laboratory workers as a result of aerosol infections from laboratory accidents and from handling of infected laboratory animals. The TC83 live attenuated VEE virus vaccine may be teratogenic in humans.

**PATHOGENESIS**

Inapparent infection is the mildest form of the disease and may be characterized by only a transient fever. A more severe form of the disease is manifested by tachycardia, depression, anorexia, occasional diarrhea, and fever.

Viremia persists throughout the course of the disease in VEE and the blood provides a source of infection for biting insects. Transplacental transmission of the VEE virus can occur in pregnant mares infected near term. The virus is present in saliva and nasal discharge, and this material can be used to transmit the disease experimentally by intranasal instillation.

Penetration of the virus into the brain does not occur in all cases and the infection does not produce signs other than fever, unless involvement of the central nervous system occurs. The lesions produced in nervous tissue are typical of a viral infection and are localized particularly in the gray matter of the cerebral cortex, thalamus and hypothalamus, with minor involvement of the medulla and spinal cord. It is this distribution of lesions that is responsible for the characteristic signs of mental derangement, followed at a later stage by paralysis. The early apparent blindness and failure to eat or drink appear to be cortical in origin. True blindness and pharyngeal paralysis occur only in the late stages.

**CLINICAL FINDINGS**

The diseases associated with the different viruses are **clinically indistinguishable**. The **incubation period** for VEE is 1–6 days. Uncomplicated disease usually lasts about 1 week. In the initial viremic stage there is fever, which may be accompanied by anorexia and depression, but the reaction is usually so mild that it goes unobserved. In the experimental disease, the temperature may reach 41°C (106°F) persisting for only 24–48 hours, with nervous signs appearing at the peak of the fever. Animals that have shown nervous signs for more than 24 hours may then have a temperature within the normal range.

**Early nervous signs** include hypersensitivity to sound and touch, and in some cases transient periods of excitement and restlessness, with apparent blindness. Affected horses may walk blindly into objects or walk in circles. **Involuntary muscle movements** occur, especially tremor of shoulder and facial muscles and erection of the penis. A stage of severe mental depression follows. Affected horses stand with the head hung low; they appear to be asleep and may have a half-chewed, mouthful of feed hanging from the lips. At this stage the horse may eat and drink if food is placed in its mouth. The pupillary light reflex is still present. The animal can be aroused, but soon relapses into a state of somnolence.

A stage of paralysis follows. There is inability to hold up the head, and it is often rested on a solid support. The lower lip is pendulous and the tongue may hang out. Unnatural postures are adopted, the horse often standing with the weight balanced on the foreleg or with the legs crossed. **Head-pressing** or leaning back on a halter are often seen. On walking, there is obvious incoordination, particularly in the hindlegs, and circling is common. Defecation and urination are suppressed and the horse is unable to swallow. Complete paralysis is the terminal stage. The horse goes down, is unable to rise and usually dies within 2–4 days from the first signs of illness. A proportion of affected horses do not develop paralysis and survive, but have persistent neurological deficits.

In the experimental infection of horses with the endemic strain of the **VEE virus**, a fever and mild leukopenia occurs. Following infection with the epidemic strain of the virus, a high fever and severe leukopenia are common, and a high level of neutralizing antibodies develop about 5–6 days after infection. Clinical findings include profound depression, accompanied by flaccidity of lips, partially closed eyelids, and drooped ears; some horses
There may be sufficient viral antigen to be detected by ELISA in clinical material, and this may provide a useful test in the early stages of an epidemic.  

**NECROPSY FINDINGS**

The brain meninges may appear congested, but there are generally no gross changes. Histological examination of the brain reveals perivascular accumulations of leukocytes and damage to neurons. The gray matter of the forebrain and midbrain are the most severely affected areas. In some cases of VEE, liquefactive necrosis and hemorrhage are visible in the cerebral cortex. Cell culture and transmission experiments utilizing brain tissue as an inoculum are the traditional means of confirming a diagnosis, and require that the brain be removed within an hour of death. Transmission is by intracerebral inoculation of brain tissue into sucking mice or duck embryo tissue culture. Fluorescent antibody tests have been developed to detect VEE virus and EEE virus in brain tissue.

**Samples for postmortem confirmation of diagnosis**

- One half of midsagittally-sectioned brain and liver and spleen should be submitted for fluorescent antibody and bioassay
- One half of midsagittally-sectioned brain, fixed in formalin, should be submitted for light microscopic examination.

**Note the zoonotic potential of these organisms when handling the carcass and submitting specimens.**

**DIFFERENTIAL DIAGNOSIS**

Clinically, the disease has very great similarity to the other viral encephalomyelitides, from which it can often be discriminated by the geographical location of the horse, and to the hepatic encephalopathies and a number of other diseases (see below and in Table 22.1).

- Rabies
- West Nile virus encephalomyelitis
- Borna disease – occurs in Europe
- Japanese encephalitis – occurs in Asia
- Various other viral infections that are geographically restricted
- Hepatic encephalopathy, such as that associated with poisoning by _Crotalaria_, _Senecio_, and _Amsinckia_ spp.; acute serum hepatitis or hepatopathy

**TREATMENT**

There is no definitive or specific treatment. Supportive treatment may be given with the intention to prevent self-inflicted injury, and maintain hydration and nutritional status.

**CONTROL**

Control of VEE of horses is based on:

- Accurate clinical and laboratory diagnosis of the disease in horses
- Use of sentinel animals to monitor the presence of the virus in the region
- Quarantine of infected horses to stop movement of virus donors
- Insect abatement when deemed necessary
- Vaccination of all horses.

**Vaccination**

Vaccination of horses is important not only because it minimizes the risk of disease in vaccinated horses but also because it prevents viremia, subsequent infection of feeding mosquitoes, and propagation spread of VEE.

One of the most important aspects of the control of VEE is the vaccination of the horse population to minimize the number of horses that are viremic and serve as amplifying hosts. A tissue culture-attenuated virus vaccine TC83, is available for immunization of horses against VEE. The vaccine is considered to be safe and efficacious, but should be reconsidered in light of the observation that the source of epidemic VEE virus is mutation of endemic strains.

A highly effective immunity is produced within a few days following vaccination, and serum neutralizing antibodies persist for 20–30 months.

The vaccine causes a mild fever, leukopenia and a viremia and, because of conflicting reports about its capacity to cause abortion, should not be used in pregnant mares. Antibodies to the heterologous alphaviruses, WEE and EEE, existing at the time of TC83 vaccination, may suppress the VEE antibody response to the vaccine.

**Botulism causes weakness evident as muscle fasciculation, recumbency and dysphagia, but does not cause cerebral signs (irritation, behavioral abnormalities)**

**Yellow star thistle poisoning ( _Centaurea solstitialis_ ) and poisoning by fumonisins can produce similar clinical signs to that of the encephalitides, with the exception of fever.**

</table>
However, the response to the vaccine is adequate to provide protection against VEE, and the interference is not considered significant. There is inconclusive evidence that WEE and EEE antibodies protect horses against infection with virulent VEE virus, or conversely that VEE antibodies protect against infection with WEE and EEE viruses. Simultaneous vaccination using formalin-inactivated EEE, WEE, and VEE (the TC83 strain of VEE) is effective and recommended in areas where all three viruses may be present.

Protection from insects
Housing of horses indoors at night, especially in flyproofed stables, and the use of insect repellents might restrain the spread of the virus. Widespread spraying of insecticides to reduce the population of the vector insects has been used in the control of VEE in humans, along with vaccination of horses. Complete eradication of the virus appears to be impossible because of the enzootic nature of the ecology of the virus: epidemic VEE arising by chance mutation of endemic strains of VEE, make elimination of the virus impossible with methods currently available.

### JAPANESE ENCEPHALITIS

Japanese encephalitis is associated with the Japanese encephalitis flavivirus (JEV), a member of the Flaviviridae family. Antigenically related viruses include Murray valley encephalitis virus, Kunjin virus, and West Nile virus. There appear to be a number of variants of JEV, with there being genetic and antigenic differences between endemic and non-endemic strains, and isolates of different years. The virus cycles between avian and mammalian amplifying hosts and the mosquitoes. The pig is the principal mammalian amplifying host among domestic animals. Horses and humans become infected but likely play only a minor role in the spread of the virus. The disease is listed by the OIE.

The disease occurs throughout the Orient and South-East Asia and has extended into Papua New Guinea, the Torres strait, and northern Australia. Outbreaks of disease occurred in the Torres strait in 1995 and disease in humans has occurred rarely in northern Australia. Outbreaks of disease have not occurred in Australia, despite large populations of wild pigs, wading birds, and mosquitoes probably because the mosquitoes prefer to feed on marsupials, which are poor hosts for JEV.

Horse deaths are now uncommon in Japan, due to vaccination of most horses, but 15–70% of race horses have antibodies to JEV that are not induced by vaccination. Seroepidemiological surveys of cattle in Japan reveal that about 68% of animals are positive. Disease in horses and humans occurs in China. The prevalence of the disease is related to the population of pigs, the main amplifying host, the mosquito vector, and susceptible human and equine hosts. Factors affecting the number of mosquitoes include availability of suitable habitat, such as rice field in which survival of mosquito larvae is enhanced by application of nitrogenous fertilizers and the presence of phytoplankton which provide food and shelter for the larvae.

The clinical manifestations of the disease in horses vary widely in severity.
Mild cases show fever up to 39.5°C (103°F), anorexia, sluggish movements, and sometimes jaundice for 2–3 days only. More severe cases show pronounced lethargy, mild fever, and somnolence. Jaundice and petechiation of the nasal mucoa are usual. There is dysphagia, incoordination, staggering, and falling. Transient signs include neck rigidity, radial and labial paralysis, and blindness. In the most severe cases there is high fever (40.5–41.5°C, 105–107°F), hyperexcitability, profuse sweating, and muscular tremor. Violent, uncontrollable activity may occur for a short period. This severe type of the disease is uncommon, representing only about 5% of the total cases, but is more likely to terminate fatally. In most cases complete recovery follows an illness lasting from 4 to 9 days. A variety of tests are available to detect antibodies to JEV. A latex agglutination test provides accurate detection of antibodies in the field. However, definitive diagnosis of Japanese viral encephalitis should not be based exclusively on serology because infection with antigenically related viruses including Murray Valley encephalitis virus, Kunjin virus, and West Nile virus can cause false-positive (from the perspective of JEV) results.

The disease in cattle, sheep and goats is usually clinically inapparent and of little overall significance. Widespread losses, however, have been reported in swine, particularly in Japan. The disease occurs as a non-suppurative encephalitis in pigs under 6 months of age. Sows abort or produce dead pigs at term. There are no characteristic gross changes. As is typical of most viral encephalitides, microscopic changes include a nonsuppurative encephalomyelitis, focal gliosis, neuronal necrosis, and neuronophagia. Isolation of this flavivirus is difficult and bioassay techniques are comparatively slow. As a result, detection via PCR is likely to be increasingly utilized. Immunohistochemistry can be used to demonstrate this virus in formalin-fixed, paraffin-embedded sections.

**Samples for confirmation of diagnosis**

- Virology – 5 mL chilled CSF fluid, chilled brain (split along midline) (ISO, BIOASSAY, PCR)
- Histology – fixed samples of other half of brain, lung, spleen, liver, heart (LM, IHC).

**Note the zoonotic potential of this organism when handling carcass and submitting specimens.**

There is no specific treatment for the disease. Control is by vaccination. Formalinized vaccines afford excellent protection in pigs and horses.

**REFERENCES**

**WEST NILE ENCEPHALITIS**

**ETIOLOGY** West Nile virus, a flavivirus

**Epidemiology** Maintained in a bird-mosquito cycle. Mammals are incidentally infected. Enzootic in Africa and, recently, North America. Epizootics in the Mediterranean littoral and southern Europe. Affects a wide variety of species including horses, humans, sheep, camelds, and dogs.

**Clinical signs** Weakness, incoordination, altered mentation, muscle fasciculations, recumbency.

**Clinical pathology** MAC-ELISA for diagnosis. Lesions Polioencephalomyelitis.

**Diagnosis confirmation** MAC-ELISA, clinical signs, lesions.

**Treatment** None specific. Supportive care.

**Control** Vaccination. Mosquito control.

**ETIOLOGY** Encephalitis in horses, humans, and other species is associated with West Nile virus, an arthropod borne flavivirus in the Japanese encephalitis virus group. Other viruses in the group include Japanese encephalitis virus (Japan and South-East Asia), St Louis encephalitis virus (United States), Kunjin virus (now considered a subtype of West Nile virus, Australia), Murray Valley encephalitis virus (Australia), and Rocío virus (Brazil). The virus was first isolated in 1937 from a human with fever in Uganda. There are at least two lineages of the virus, with one lineage (lineage 1) isolated from animals in central and North Africa, Europe, Israel, and North America whereas the other (lineage 2) is enzootic in central and southern Africa. The recent outbreak in North America was associated with a virus identical to that isolated from diseased geese in Israel. Viruses of both lineages can circulate at the same time in the same geographic region. Virus of either lineage can cause disease, although that of lineage 1 appears to be associated with more severe disease in horses and other species. There are anecdotal reports of Kunjin virus being associated with isolated cases of encephalomyelitis in horses in Australia.

The West Nile virus causes disease in humans, horses, birds (including geese, raptors, and corvids), sheep, alpacas, and dogs. **EPIDEMIOLOGY**

**Distribution** West Nile encephalitis virus is enzootic to Africa and sporadic outbreaks of the disease occurred in the 1960s in Africa, the middle East and southern Europe. Recently, outbreaks affecting horses and other animals have occurred in southern France, Tuscany, Israel and other parts of southern Europe. The virus was introduced into New York city in North America in 1999 and subsequently spread widely across the continent, including Canada, Mexico and the Caribbean, in the next several years, and reaching the west coast by 2004. The virus caused widespread deaths of wild birds and disease and death in humans, horses and other species in North America during this period. Introduction of the infection to North America was associated with an epizootic of disease that over several years moved across the continent. During the initial years of the epizootic there were large numbers of cases in horses (15 000) and humans (4000) and death of at least 16 500 birds. As the front of the epizootic moved across the country, the infection became enzootic and the number of cases in horses in these regions decreased markedly over those in the first year.

**Viral ecology** The virus is maintained by a cycling between amplifying hosts, usually birds, and insect vectors. Large mammals, including horses and humans, are incidentally infected and are not important in propagation of the virus. Amplifying hosts are those in which the viremia is of a sufficient magnitude and duration (1–5 days) to provide the opportunity to infect feeding mosquitoes. Mammals, and in particular horses, are in general not amplifying hosts because of the low level of viremia. The virus is spread by the feeding of ornithophilic mosquitoes, usually of the genus Culex. Infected mosquitoes carry the virus in salivary glands and infect avian hosts during feeding. The virus then multiplies in the avian host causing a viremia that may last for up to 5 days. Mosquitoes feeding on the avian host during the viremic phase are then infected by the virus. This pattern of infec-
tion of amplifying hosts and mosquitoes is repeated such that the infection cycles in these populations. Increases in mosquito number, such as occur at the end of the summer, and enhanced viral replication in mosquitoes at higher ambient temperatures, increase the likelihood that avian hosts, or incidental hosts, will become infected. This results in an increase in the incidence of disease in late summer and early autumn.16-19

The principal avian host and vector species vary markedly between geographic regions. In North America the house sparrow (Passer domesticus) is the principal amplifying host and Culex pipiens is the principal vector. Culex pipiens, and other mosquito vectors, feed almost exclusively on passerine and columbiform birds early in the season, but later in the summer in temperate regions switch to feeding on mammalian hosts.20 This change in feeding behavior is associated with increased frequency of infection and disease in mammals, including horses and humans, in the late summer.

The virus cycles between the avian host and insect vectors year round in tropical regions. However, in temperate regions in which mosquitoes do not survive during the winter the mechanism by which the virus survives over winter is unknown.13

Transmission
Transmission is only by the bite of infected insect vectors. There is no evidence of horizontal spread of infection among horses. The disease can be spread in horses by transfusion of blood or transplantation of organs obtained from an infected person.21

Animal risk factors
The disease occurs in parts of the world as epidemics apparently associated with sporadic introduction of the virus into non-endemic regions, such as the Mediterranean littoral. Introduction of the virus to these regions occurs infrequently enough that horses have no active immunity and are susceptible to infection and disease. Horses immune through either natural infection or vaccination are resistant to the disease. The effect of immunity was evidenced in North America by the marked decrease in morbidity and mortality among horses after the epizootic waned and the disease became enzootic. The decrease in morbidity was attributed to both natural and vaccinal immunity. Interestingly, although the number of cases in horses decreased rapidly there was not a similar decrease in the number of human cases, perhaps because of the lack of a vaccine for use in humans.13

Horses of all ages appear to be equally susceptible to infection. Disease is report in horses aged from 5 months to >20 years. There does not appear to be any predilection based on breed or sex.16

Morbidity and case fatality
The incidence of the disease during an epizootic can be as high as 74 cases per 1000 horses at risk.17 The case fatality rate among horses treated in the field is 22-38%.16,17,22 whereas it is 30-43% of horses in referral centers.19,23

Zoonotic implications
Infection of humans by West Nile virus can result in fatal encephalitis, although less severe disease or apparent infection is more common. The virus has zoonotic potential and tissues from potentially infected animals and virus cultures should be handled in containment level 3 facilities, particularly material from potentially infected birds.24

PATHOGENESIS
Horses are infected by the bite of infected mosquitoes. Feeding by as few as 7 infected mosquitoes is sufficient to cause infection in seronegative horses.15 Viremia, which persists for less than 2 days, occurs 2 to 5 days after feeding by infected mosquitoes.15 West Nile encephalitis occurs in only a small proportion of infected horses. The virus localizes in cells in the central nervous system where it induces a severe polioencephalomyelitis with the most severe lesions being in the spinal cord.25 Lesions are often evident in the ventral horn of the spinal cord, which is consistent with clinical signs of weakness.

CLINICAL FINDINGS
The incubation period after natural infection is estimated to be 8–15 days. Fever occurs early in the disease but is uncommon at the time that signs of neurologic disease become evident.16,17 Affected horses are often somnolent, listless, or depressed although hyperexcitability has been reported. The signs of neurologic disease, including muscle fasciculation, weakness, and incoordination, develop within a period of hours and may progress over several days. Muscle fasciculations are common in the head and neck, but can occur in any muscle group. Weakness is most pronounced in limb and neck muscles and severely affected horses are recumbent with flaccid paralysis. Signs of neurologic disease are usually, but not reliably, bilaterally symmetrical. Altered mentation, blindness, and cranial nerve abnormalities, if they occur, usually become evident after signs of spinal cord disease are apparent.

Weakness with or without ataxia is present in almost all affected horses, whereas altered mentation is detected in approximately 66% of horses.19 Cranial nerve abnormalities are evident in approximately 40% of horses, whereas apparent blindness or lack of menace reflex occurs in 3-7% of horses.17,19

Median recovery time for horses treated in the field is 7 days, with a range of 1–21 days.17

The prognosis depends on the severity of clinical signs. Horses that become recumbent and unable to rise are approximately 50 times more likely to die than are horses that remain able to stand while affected by the disease.22 Most horses that survive the initial disease do not have signs of neurologic dysfunction 6 months later.19

Other species
Disease associated with West Nile virus is documented in small numbers of other species, including squirrels, chipmunks, bats, dogs, cats, reindeer, sheep, alpacas, alligator and a harbor seal during intense periods of local viral activity.24 The disease in camels is characterized by acute recumbency and altered mentation.5,5

CLINICAL PATHOLOGY
Affected horses are often mildly lymphopenic, and hyperbilirubinemic (likely due to anorexia), and occasionally azotemic.19 These changes are not diagnostic of West Nile encephalitis.

Cerebrospinal fluid is abnormal in approximately 70% of horses with signs of neurologic disease. Abnormalities include mononuclear pleocytosis and elevated total protein concentration.26

Serological tests
Antibody can be identified in equine serum by IgM capture enzyme-linked immunoabsorbent assay (IgM capture ELISA, MAC-ELISA), hemagglutination inhibition (HI), IgG ELISA or plaque reduction neutralization (PRN).22 Equine WN-specific IgM antibodies are usually first detectable 7–10 days after infection and persist for 1–2 months.15 Because the incubation period of the disease after infection by bite of infected mosquitoes is at least 8 days, West Nile-specific IgM is usually present at the time of development of clinical signs of the disease. The MAC-ELISA is therefore a useful test in the diagnosis of the disease.19

WNV neutralizing antibodies are detectable in equine serum by 2 weeks post-infection and can persist for more than 1 year. In some serological assays, antibody cross-reactions with related flaviviruses (St Louis encephalitis virus or Japanese encephalitis virus), can be encountered.23 The PRN test is the most specific among WN serological tests and all affected horses have titers ≥1:100 4–6 weeks after recovering from the
disease, and 90% of horses maintain this titer 5–7 months after recovery.27
Detection by MAC-ELISA of West Nile specific IgM in serum at dilutions greater than 1:400, in the presence of appropriate clinical signs, is considered diagnostic of WNV.28 Similarly, a four-fold increase in PRN titer in serum collected during the acute and convalescent stages of the disease, in the absence of vaccination and in the presence of appropriate clinical signs is considered diagnostic. Identification of WNV
The virus can be grown in cell culture and viral nucleic acid can be demonstrated in tissues of infected animals by RT-PCR.29 Note that infected horses have much lower concentrations of virus than do infected birds, and failure to demonstrate viral antigen in infected horses is not uncommon, especially if less sensitive techniques, such as immunohistochemistry, are used.24,25

Necropsy findings
Gross lesions are infrequently seen. When present they consist of multifocal areas of congestion and hemorrhage within the medulla oblongata, midbrain, and spinal cord. Histopathologic changes include a nonsuppurative poliomeningoencephalomyelitis with multifocal glial nodules and neuronophagia. The inflammatory changes and viral distribution are concentrated in the rhombencephalon and spinal cord, with comparatively little damage to the cerebrum. One immunohistochemical study of naturally infected horses concluded that examination of the spinal cord is required to accurately identify WNV infection.28 Another report, in which RT-PCR was employed, concluded that high quality samples of medulla were sufficient to detect the presence of the virus.30 Postmortem confirmation of the diagnosis through virus isolation is possible but the sensitivity is generally inferior to molecular biology-based techniques. RT-PCR is generally superior to IHC. The processing of tissue from multiple CNS sites is recommended in order to increase the chances of finding a virus-rich focus. High concentrations of WNV are not found in non-CNS tissues of infected equids, in contrast to the distribution of the virus in many other species.

Samples for confirmation of diagnosis
Virology – minimum sample is one half of sagittally sectioned hindbrain (must include medulla). Ideally a segment of thoracolumbar spinal cord as well. Submit samples chilled (VI, RT-PCR).

Histology – same samples, fixed in formalin (LM, IHC, RT-PCR).

Note the zoonotic potential of this disease when collecting and submitting specimens. Some authorities recommend using containment level 3 precautions when handling potentially infected tissues, such as that from birds.24

Treatment
There is no specific treatment for West Nile encephalitis although administration of interferon or hyperimmune globulin has been advocated. Affected horses are often administered non-steroidal anti-inflammatory drugs such as flunixin meglumine, dimethyl sulfoxide, or corticosteroids in an attempt to reduce inflammation in neural tissue.19 Administration of corticosteroids minimally but statistically significantly increases the likelihood of survival22 but this practice is controversial. Treatment is based on supportive care and prevention of complications of neurologic disease and includes assistance to stand, including use of a sling support, administration of antimicrobials, and maintenance of hydration and nutrition.

Control
Control of disease associated with West Nile virus is achieved by vaccination and minimization of exposure. Elimination of the virus is not practical given that it cycles through avian and insect vectors and that the horse is incidentally infected.

Vaccination is believed to be effective in preventing development of disease, and has been demonstrated to reduce the likelihood of death in horses with West Nile encephalitis by approximately 2–3 times.17 Efficacy of vaccination in preventing disease in horses has not been formally demonstrated although there is general agreement that vaccination is an important aspect to control of the disease.13 There is no evidence that administration of the inactivated virus vaccine increases the risk of fetal loss in mares.31 Vaccination prevents viremia in most horses following exposure to WNV-infected mosquitoes.32

Both inactivated virus vaccine and a live canarypox-vectored recombinant vaccine are available in North America. The inactivated virus vaccine should be administered in two doses at an interval of 3–6 weeks in early summer in the first instance, and then again once to twice yearly before the season of peak disease incidence. Foals from unvaccinated mares should be administered the vaccine beginning at 2–3 months of age, and foals of vaccinated mares should be administered the vaccine beginning at 7–8 months of age.

Administration of the recommended two doses of inactivated virus vaccine fails to induce an adequate plaque reduction titer in approximately 14% of horses 4–6 weeks after vaccination, and in 30% of horses 5–7 months after vaccination.27 This effect was especially evident in horses >10 years of age.27 These results indicate that some horses will not develop protective immunity against WNV despite administration of vaccine in the recommended dose and interval.

Minimization of exposure of horses to the virus includes reducing the population density of mosquitoes and protecting horses from being bitten. Reducing the population of mosquitoes includes widespread spraying with insecticides and elimination of mosquito breeding sites. Widespread spraying in cities is employed when the disease is a risk for humans but is not practical for controlling mosquitoes in rural areas. Environmental concerns make this approach to control unacceptable in many regions.

Removal of larval habitat by draining standing water is recommended for control of WNV, although the efficacy of this approach has not been demonstrated. Standing water includes not just dams and ponds but also poorly maintained outdoor swimming pools, bird baths, discarded vehicle tires, and other receptacles that could hold water. Use of larvicidal compounds in standing water is recommended by some authorities.

Minimizing the frequency with which horses are bitten by mosquitoes has the potential to reduce the risk of contracting the disease. However specific recommendations are not available. Housing during peak mosquito activity, especially at dawn and dusk, might reduce the risk of disease.

Review literature
Borna disease virus (BDV) is suspected of causing disease in humans, including lymphocytic meningoencephalitis, but BDV infection is not associated with an increased prevalence of psychiatric disorders. Others suggest that the presence of circulating BDV immune complexes (BDV antigen and specific antibodies) is associated with severe mood disorders in humans. The role, if any, of BDV in human neurologic or psychiatric disease has not been established with any certainty.

Detection of BDV genome by PCR analysis suggests that, while the spontaneous disease in horses and sheep occurs predominantly if not exclusively in Europe, clinically unapparent BDV infection is widespread in a number of species including horses, cattle, sheep, cats, and foxes. However, concern has been raised that some of these reports might be based on flawed laboratory results as a consequence of contamination of PCR assays. Antibodies to BDV in serum or cerebrospinal fluid have been detected in horses in the eastern United States, Japan, Iran, Turkey, France, and China, and in healthy sheep and dairy cattle in Japan. In areas in which the disease is not endemic between 3% (US) and 42% (Iran) of horses have either antibodies or BDV nucleic acid, detected by PCR, in blood or serum. Similarly, approximately 12–20% of horses have serological evidence of exposure to BDV in areas of Europe where the disease is endemic. Antibodies to BDV and nucleic acid have been detected in humans in North America, Europe, and Japan. The role of BDV in human neurologic or psychiatric disease has not been established with any certainty.

The possibility of vertical transmission is unknown, but it is thought to be horizontal by inhalation or ingestion. Seropositive, clinically normal horses and sheep can excrete virus in conjunctival fluid, nasal secretions and saliva, suggesting that they might be important in the transmission of infection. Removal of all seropositive and BDV RNA positive sheep from a closed flock did not prevent seroconversion of other animals in the flock the following year. The possibility of vertical transmission is raised by the finding of BDV RNA in the brain of a fetal foal of a mare that died of Borna disease.

There is a seasonal distribution to the prevalence of the disease, with most cases in horses occurring in spring and early summer. The virus has not been isolated from arthropods, including hematophagous insects.

The morbidity in Borna disease is not high, approximately 0.006–0.23% of horses affected per year in endemic areas of Germany, but most affected animals die.

The pathogenesis of the disease involves infection of cells of the central nervous system. It is assumed that the virus gains entry to the central nervous system through trigeminal and olfactory nerves, with subsequent dissemination of infection throughout the brain. Viral transcription and replication occurs within the cell nucleus. Viral replication does not appear to result in damage to the infected neuron. However, infected cells express viral antigens on their surface which then initiate a cell-mediated immune response by the host that then destroys infected cells — immunosuppression prevents development of the disease. The inflammatory response is largely composed of CD3+ lymphocytes. The disease is subacute; infection and the development of lesions may take weeks to months. Clinically apparent infection appears to be common in a number of species, including horses.

In field outbreaks the incubation period is about 4 weeks, and possibly up to 6 months.

Clinical signs of the disease in horses include:

- Moderate fever
- Pharyngeal paralysis
- Lack of food intake
- Muscle tremor
- Defects in proprioception
- Hyperesthesia

Lethargy, somnolence and flaccid paralysis are seen in the terminal stages, and death occurs 1–3 weeks after the first appearance of clinical signs. Infection without detectable clinical signs is thought to be common on infected premises. The frequency with which BDV is detected in horses with gait deficits is greater than in clinically normal horses, suggesting a role for the virus in inducing subtle disease.

The disease in cattle has a similar presentation as that in horses, with affected animals having reduced appetite, ataxia, paresis, and compulsive circling. The disease ends in the death of the animal after a 1-6-week course.

Hematology and routine serum biochemistry are typically normal, with the exception of fasting induced hyperbilirubinemia in anorexic horses. Clinico-pathological identification of exposed animals is achieved with the complement fixation, ELISA, western blot, or indirect immunofluorescent tests.

At necropsy there are no gross findings, but histologically there is a lymphocytic and plasmacytic meningoencephalitis, affecting chiefly the brain-stem, and a lesser degree of myelitis. The highest concentration of virus is in the hippocampus and thalamus. The diagnostic microscopic finding is the presence of intranuclear inclusion bodies within neurons, especially in the hippocampus and olfactory bulbs. The virus can be grown on tissue culture and demonstrated with immunoperoxidase techniques.

There are a number of Bunyaviridae that can cause disease in horses in the western hemisphere. The viruses are maintained in a mosquito-vertebrate host-mosquito or midge-vertebrate host-midge cycles with horses being infected and developing signs of neurologic disease occasionally.

The California serogroup of viruses are mosquito-transmitted viruses of the family Bunyaviridae which can cause acute encephalitis in horses. There are 12 serotypes isolated in Africa, Europe, Asia, and North and South America. Snowshoe hare and Jamestown Canyon are two of these serotypes that have been isolated in Canada and California, and that have the potential to cause disease in humans. The snowshoe hare virus is the most widely occurring arbovirus in Canada and is maintained in an amplification cycle involving small mammals, such as snowshoe hares, and mosquitoes, primarily of the genus *Aedes*. In one reported case, the horse recovered completely within 1 week and there was seroconversion to the snowshoe hare serotype of the California serogroup of viruses. Approximately 15% of horses in California have antibodies to *Jamestown Canyon virus* in horses in southern California. The virus has been isolated from vesicular lesions in a horse.

The Cache Valley virus has been isolated from a clinically normal horse and the high seroprevalence of specific antibody suggests enzootic transmission.

The Main Drain virus has been isolated from a horse with severe
enveloped viruses with a single-stranded, positive sense RNA genome. Getah virus causes disease in horses and pigs, whereas Ross River virus causes disease in humans and, arguably, horses.

The geographic range of the viruses is distinctive, with Getah virus reported from Japan, Hong Kong, south-east Asia, Korea, and India, and Ross River virus found in most areas of continental Australia, Tasmania, West Papua and Papua New Guinea, New Caledonia, Fiji, Samoa, and the Cook Islands. Reports from the 1960s document antibodies to Getah virus in animals in Australia, but the presence of this virus in Australia has not been confirmed using modern techniques that are able to differentiate antibodies to Getah virus from those of the related Ross River virus and other viruses in this complex. There are no reports of disease caused by Getah virus in Australia. There is considerable sequence homology between Getah and Ross River virus genomes. There is geographic genetic variability among isolates of Ross River virus, and temporal, but not geographic, variability among isolates of Getah virus from South-east Asia and Japan. \(^3,^4\)

Both viruses are arthropod-borne, and infection is through the bite of an infected mosquito. The virus is maintained in the mosquito-vertebrate-mosquito host cycle typical of arboviruses. The definitive, amplifying vertebrate host for Getah virus is unknown although a number of vertebrates including horses, cattle and pigs can be infected by the virus. Horses and pigs become viremic and presumably can infect mosquitoes, although this does not appear to have been confirmed experimentally. The life cycle of Getah virus has not been explicated. The virus is assumed to be maintained in a mosquito–pig–mosquito cycle in those areas in which there is mosquito activity year round. \(^5\) Persistence of the virus in areas in which mosquito activity is seasonal has not been explained, and whether transovarial or transstadial transmission occurs within the mosquito population is not reported. \(^5\) The vertebrate hosts of Ross River virus include a large number of eutherian, marsupial, and monotreme mammals and birds. \(^5\) Macropod species, including kangaroos and wallabies, are assumed to be the most important amplifying hosts, although this is debated. \(^1\)

There is suspicion that during outbreaks of disease Getah virus is spread by horse-to-horse contact, based on the rapidity of spread among horses, the short duration of the outbreak, and the lack of mosquito activity at the time that some horses developed the disease. \(^5,^7\) However, experimental evidence suggests that this route of spread is likely of limited importance in propagation of epidemics because of the low concentration of virus in nasal and oral secretions of infected horses, and the large inoculum required to cause disease in horses by the intranasal route. \(^8\)

The prevalence of serological evidence of infection of horses by Getah virus in Japan ranges from 8 to 93%, depending on the region of the country in which the samples were collected and the disease history of the band or stable of horses. \(^6,^9\) Seroprevalence was 17% in India and 25% in Hong Kong. \(^8,^{10}\) These results confirm the widespread incidence of subclinical infection of horses by Getah virus in endemic areas.

There is a similar high incidence of Ross River virus infection of horses in endemic regions of Australia. Prevalence of seropositive horses in Queensland, an area in which year-round mosquito activity was likely, is approximately 80%, whereas that of horses around the Gippsland lakes in southern Australia, a region with seasonal mosquito activity, is 50%. \(^11\) These high rates of infection, in the absence of similarly high rates of clinical disease, suggest that the virus is minimally pathogenic in horses, and increases the likelihood that seroconversion or virus isolation from horses with clinical abnormalities is a chance event and not causally related.

The disease syndrome caused by infection with Getah virus is better defined than that of Ross River virus, but infection by either virus appears to cause disease in horses that has a number of clinical features in common. \(^6,^{11,^{12}}\) Disease associated with Getah virus infection is characterized by pyrexia, edema of the limbs, and an abnormal gait, often described as 'stiffness'. \(^6,^7\) Eruptions of the skin, urticaria, and submandibular lymphadenopathy are reported in some horses with the disease in Japan, but not in India. \(^6,^7\) The clinical disease persists for 7–10 days. Abortion is not a feature of the disease and foals born of mares that have had the disease during gestation are normal. \(^3\) Subclinical infection is very common.

Hematological abnormalities induced by Getah virus infection in horses include lymphopenia. \(^3\) Increases in serum activity of muscle derived enzymes, such as creatine kinase, are not characteristic of the disease. Affected horses can have mild to moderate hyperbilirubinemia secondary to inappetance. \(^5\)

The disease associated with Ross River virus infection of horses is typified by pyrexia, lameness including 'stiffness', swollen joints, inappetance, reluctance to move, and mild colic. \(^3,^{11,^{12}}\) The duration of disease caused by Ross River virus in horses is uncertain, and some veterinarians consider that the disease is mild. \(^6\)
Pathogenic Getah virus typically have mild changes including atrophy of splenic and lymphoid tissue with destruction of lymphocytes, and perivascular and diffuse infiltration of focal skin lesions by lymphocytes, histiocytes, and eosinophils. Lesions in the central nervous system are equivocal and limited to mild perivascular cuffing in the cerebrum and small hemorrhagic foci in the spinal cord.\textsuperscript{13}

Treatment of affected horse is supportive. Affected horses might benefit from administration of analgesics and antipyretics such as phenylbutazone. Administration of antimicrobials is not indicated in uncomplicated cases.

An inactivated virus vaccine is available in Japan for immunization of horses against disease caused by Getah virus.\textsuperscript{9} The vaccine, which is combined with that for Japanese encephalitis, is considered effective. For both Getah virus and Ross River virus minimizing the exposure of horses to infected mosquitoes is prudent although the efficacy of this technique in preventing infection is unknown. During outbreaks of disease caused by Getah virus it is prudent to isolate affected horses, given the potential for horse-to-horse spread of the virus.

There is no vaccine to prevent infection or disease of horses by Ross River virus.

Zoonotic implications
Disease of humans caused by Getah virus has not been documented.

Disease associated with Ross River virus infection is common in humans in Australia with an estimated 4800 cases per year, and much larger numbers during epidemics of the disease.\textsuperscript{10} The horse is believed to be an amplifying host of the virus because experimentally infected horses can infect mosquitoes.\textsuperscript{16} The disease in humans is characterized by mild pyrexia and constitutional signs initially, with subsequent development of a rash on the skin and oral lesions. Arthritis or arthralgia is common and affects primarily the wrists, knees, ankles and small joints of the extremities. These signs and symptoms can persist for 2–3 months, and the disease can relapse.

RABIES

Etiology
Lyssavirus of family Rhabdoviridae

Epidemiology
Occurs in all farm animals worldwide except Australia and New Zealand. Major zoones. Transmitted by bites of infected animal. Many different wildlife are vectors depending on geographic location; vampire-bats in South America, foxes in Europe and North America, skunks in North America, mongoose in Africa, raccoon in the United States recently.

Signs
Incubation period varies from 2 weeks to several months. Cattle – Paralytic form: bizarre mental behavior (yawning, bellowing), incoordination, decreased sensation of headquaters, drooling saliva, recumbency, and death in 4–7 days. Furry form: hypersensitive, belligerent, then paralysis and death as in paralytic form. Sheep – Outbreaks common; sexual excitement, wool pulling, attacking, incoordination, and then paralysis. Horses – Abnormal postures, lameness or weakness, depression, ataxia, pharyngeal paralysis, recumbency, hyposthesia, biting, loss of anal sphincter tone, death in 4–6 days. Pigs – Excitement, attack, twitching of nose, clinic convulsions, paralysis.

Clinical pathology
No antemortem test

Lesions
Non-suppurative encephalomyelitis

Differential diagnosis list:
• Cattle: Lead poisoning, lactation tetany, hypovitaminosis-A, listerial meningoencephalitis, polioencephalomalacia, nervous acetonemia
• Horse: Viral encephalomyelitis, herpes viral paralyis, cerebrospinal nematodiasis, equine degenerative myeloneuropathy, protozoal encephalomyelitis, neoplasia of cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism
• Sheep: Enterotoxemia, pregnancy toxemia, luping-ill, scrapie
• Pigs: Pseudorabies, Teschen’s disease, Glasser’s disease, and other meningitides (E. coli and Streptococcus aus)

Diagnostic confirmation
Fluorescent antibody test of brain. Negri bodies histologically

Treatment
None. All rabies cases are fatal.

Control
Prevention of exposure. Vaccination of domestic animals and wildlife. Quarantine and biosecurity to prevent entry of virus into country.
ETIOLOGY
Rabies is associated with the rabies virus of the genus Lyssavirus of the family Rhabdoviridae. The genus is composed of at least six genotypes.

It was recognized long ago that the strain of virus known as the 'street' rabies virus differed in some way from 'fixed' strains which had been cultivated for vaccine production (grown in cell culture or passaged through serial generations of laboratory animals). It is now known that there are several strains of rabies virus, which are adapted to particular host species but remain infective for any warm-blooded mammal.

EPIDEMIOLOGY
Occurrence
Rabies occurs in all warm-blooded animals. The disease occurs in cattle, sheep, pigs, and horses in most countries, except the insular countries that exclude it by rigid quarantine measures or prohibition of the entry of dogs. However, the genus Lyssavirus can still cause surprises. In 1996 and 1998, two women died in Queensland, Australia, from infections with a newly discovered rabies-related virus (Australian bat lyssavirus). In 2002, a man died in Scotland after contracting European bat lyssavirus rabies indicating that after a century of apparent freedom from rabies, the disease is now enzootic in the UK.

South America, Latin America and the Caribbean
Rabies in cattle is a major economic and public health problem in South America, where vampire bat-transmitted rabies results in cyclic outbreaks. Bovine paralytic rabies is endemic in the tropical regions extending from northern Mexico, to northern Argentina, and on the island of Trinidad. An outbreak in cattle in Guyana was associated with a large number of bats that had inhabited a culvert that was not cleaned regularly because of excessive rainfall.

Europe
In Europe, sylvatic rabies is a major problem where the red fox is the principal vector. The disease is still spreading from a focal point that developed in Poland in the mid-1930s. It is endemic in Yugoslavia and Turkey, and has spread westward to Germany, Denmark, Belgium, Czechoslovakia, Austria, Switzerland, and France. Spread continues at the rate of about 30-60 km (18-37 miles) per year and the threat to the United Kingdom increases each year. Finland had been free of rabies since 1959, but in 1988 sylvatic rabies occurred with the raccoon dog as the vector. Monoclonal antibody indicated the virus was an Arctic-type strain possibly related to the red fox. France reported more than 2000 cases of rabid cattle between 1968 and 1982, and had more cases in sheep than in either dogs or cats during the same time period. In former East Germany, sheep were the second most frequent animal diagnosed with rabies after foxes.

Epidemiological studies of rabies in Lithuania from 1990 to 2000 found that rabies among wildlife comprised 54% with the majority of cases in foxes (27%), followed by raccoon dogs (21%). The incidence of rabies in foxes and raccoon dogs increased over the period of study. Also, the number of humans attacked by domestic animals and wild animals has increased.

Africa
Rabies occurs in most countries in the African continent, but the reported incidence is surprisingly low for an area with such a high population of wild carnivores. The incidence of rabies, and the range of species involved, is increasing in Africa, and a number of wildlife hosts has been identified, including wild dogs, jackals and mongoose. Because of displacement of civilian life, rabies in Zimbabwe has increased in prevalence and geographical distribution in recent years.

Rabies is now a very serious zoonotic disease in South Darfur, Sudan. South Africa
Over a 4-year period, of all the domestic animal rabies cases reported, cattle accounted for one-half of the rabies cases in South African domestic animals. The mongoose accounted for 70% of the wild animal cases reported. Widespread distribution of the rabies virus occurs when the young mongooses are evicted from their parents' territory during the winter months, forcing them to scatter over a wide area. This increases the probability of domestic animals coming in contact with rabid animals.

Canada
The arctic fox variant of rabies invaded most of Canada south of 60°N and east of the Rocky Mountains in the early 1950s largely by the migration of arctic foxes into the populated areas. It died out in most of that range, but persisted for over 40 years in southern Ontario with sporadic incursions into narrow adjacent strips in western Quebec and northern New York. The principal vectors were red foxes (Vulpes vulpes) and, to a lesser extent, striped skunks (Mephitis mephitis). During the period 1957 to 1989, Ontario experienced more animal rabies cases than any almost every North American jurisdiction almost every year, and over 95% of those cases were limited to the southernmost 10% of the province's land area.

A second major outbreak, involving striped skunks, progressed from North Dakota into the prairie provinces during the late 1950s and 1960s. In the 1990s, the endemic areas in Canada are southern Ontario, which accounts for 85% of the Canadian diagnoses, and the prairie provinces where rabies is endemic in skunks. In western Canada, the main reservoirs of the rabies virus are skunks, bats, and foxes.

In southern Ontario, Canada, the ecogeographic patterns of rabies indicate that townships could be aggregated into 12 rabies units or clusters. The units had different behaviors in terms of species composition, persistence, and periodicity. The ratio of rabid skunks to rabid foxes varied between areas which may be due to seasonal factors and urban development. This information is useful for planning rabies control programs.

United States
Information on rabies surveillance in the United States is published annually by the Centers for Disease Control and Prevention. From 1999 to 2003, more than 90% of cases occurred in wild animals, 6 to 9% in domestic animal species. The disease occurred in humans, raccoons, skunks, bats, foxes, cats, dogs, cattle, sheep and goats, horses and mules, mongoose, rodents and lagomorphs.

Most cases of rabies reported annually in the United States occur among three groups of carnivores: raccoons, skunks, foxes, and among bats. However, between 1960 and 2000, a total of 2851 cases of rabies in 17 other carnivore taxa were reported to the Centers for Disease Control and Prevention, Atlanta, Georgia. Three species of other carnivores (mongooses, coyotes, and bobcats accounted for 92% of the cases reported among other carnivorous mammals. The most frequently reported rabid wildlife cases occurred in raccoons, skunks, bats, and foxes. The relative contributions of those species continue to change in recent decades because of fluctuations in enzootics of rabies among animals infected with several distinct variants of the rabies virus.

During the past 30 years, rabies in domestic animals has steadily decreased in the United States, whereas annual occurrence in wild animals has increased. Wild animals accounted for 92% of all reported cases of rabies in 1995, a decrease from 1994. Raccoons were the most frequently reported rabid animal (50.3% of all animal cases), followed by skunks (22.5%), bats (10.0%), foxes (6.5%) and other wild animals, including rodents and lagomorphs (2.7%). Domestic animals accounted for nearly 8% of all rabid animals in the United States in
In recent years, the number of rabid cattle was equal to, or greater than, the number of rabid dogs. The incidence of rabies in horses is low compared to other domestic small animals but rabies in horses is 'low compared to Virginia to raccoons in Georgia, Alabama, Florida to raccoons in the United States is about 1995. In recent years, the number of rabid cattle was found to be similar to the number of rabid dogs. The incidence of rabies in horses is low compared to other domestic small animals but rabies in horses is 'low compared to Virginia. 

In 1990, for the first time since surveillance began in 1950, the number of cases in raccoons exceeded that in skunks. Raccoon rabies spread from Florida to raccoons in Georgia, Alabama, South Carolina, and North Carolina by natural spread. A separate focus in the northeastern States was caused by a translocation of raccoons from Florida, with legal permits to Virginia for restocking cattle was equal to, or greater than, the number of cases of rabies in skunks. From the index case in a raccoon in 1977, near the Virginia–West Virginia border, over the next 17 years, 20 000 cases of rabies were recorded in raccoons, and several thousand associated cases in domestic dogs and other animals. In Canada, the rabies virus isolates from raccoons-positive raccoons from 1982 to 1994 were the same strains found in foxes and skunks in eastern Canada, and is different from the 'Mid-Atlantic' strain found in raccoons in the United States. Local dynamics of epidemics of raccoons in raccoons in the United States can be predicted.

Historically, in North America, the number of cases of rabies in skunks exceeded that in either raccoons or foxes. Endemic skunk rabies occurs mainly in four geographical regions: southern Ontario and Quebec and upper New York State; the north central United States and the Canadian provinces of Manitoba, Saskatchewan, and Alberta; California; and south central United States. Within these broad areas, the disease persists in enzootic foci and erupts every 6–8 years. Experimental studies suggest that the species specificity of endemic rabies is due to differences in the pathogenicity of variants of rabies virus. Skunk rabies peaks in the spring and early winter, which is probably a reflection of certain life history events within the skunk population.

The prevalence of rabies in bats in the United States is about 6%, and transmission to humans is rare even though sensational journalism has caused many people to consider bats as a serious threat to health. All of the confirmed cases of rabies in bats in Michigan in 1993 were associated with the big brown bat; in New York the prevalence in 1993 was 4.6% and nearly 90% of rabid bats were the common big brown bat. However, the silver-haired bat was associated with two human cases of rabies.

Trends in national surveillance for raccoons among bats in the United States from 1993 to 2000 have consistently found a diffuse geographic pattern of raccoons throughout the continental United States. Although spillover infection of bat variants of raccoons among terrestrial animals such as dogs and cats are rare, these variants of raccoons have been associated with 92% of the indigenously acquired human rabies infections in the United States since 1990. Data from 37 states from 1993 to 2000 indicate an increased risk of rabies among certain groups of bat species was consistently found across season and most geographic regions of the US. The Brazilian free-tailed, eastern pipistrelle, and the silver-haired bats, when considered as a single group, were more rabid more frequently than were other bat groups.

All warm-blooded animals, with the possible exception of opossums, are susceptible, and there is no variation in susceptibility with age; 1-day-old pigs have been affected. Variation in susceptibility between species is noticeable. Foxes, cotton rats, and coyotes are extremely susceptible; cattle, rabbits, and cats are highly susceptible; dogs, sheep, and goats are moderately susceptible; and opossums little if at all.

**Distribution of virus variants**

The *Lyssavirus* genus belongs to the *Rhabdoviridae* family of the *Mononegavirales* order and includes unsegmented RNA viruses causing rabies encephalomyelitis. They are well fitted to vectors belonging to the orders Carnivora (flesh-eating mammals including skunks), and Chiroptera (the order which comprises all of the 178 genera in 16 families of bats). Seven genotypes have so far been delineated within the genus. These genotypes are divided into two immunologically and genetically distinct phylogroups. Phylogroup I includes two African genotypes: *Mokola virus*, which has been isolated from shrews and cats, although its reservoir remains unknown, and *Lagos bat virus*, which has been found mainly in frugivorous bats but also in an insectivorous bat. Phylogroup II has five genotypes: *Duvenhage virus* (Africa), *European bat lyssavirus 1* (EBLV-1; Europe), EBLV-2 (Europe), *Australian bat lyssavirus* (Australia), and the classical *Rabies virus* (RABV, worldwide). Members of the genotypes *Duvenhage virus*, EBLV-1, and EBLV-2 are exclusively found in insectivorous bats, members of the genotype *Australian bat lyssavirus* are found in both insectivorous and frugivorous bats, and member of the genotype RABV are found in carnivorous and American bats (insectivorous, frugivorous, and hematophagous). The fact that lyssaviruses are well established in two ecologically distinct mammal orders may very likely be the consequence of successful host switching.

Analysis of 36 carnivoran and 17 chiropteran lyssaviruses representing the main genotypes and variants strongly supports the hypothesis that host switching occurred in the history of the lyssaviruses. In fact, lyssaviruses evolved in chiroptera long before the emergence of carnivoran rabies, very likely following spillovers from bats. Using dated isolates, the emergence of carnivoran rabies from chiropteran lyssaviruses is estimated to have occurred 888 to 1459 years ago.

In Europe, bat rabies is associated with two specific virus strains: European bat lyssavirus type 1 and European bat lyssavirus type 2. European bat lyssavirus type 1 isolates have been found in serotine bats in France. European bat lyssavirus type 2 virus have now been found in Daubenton's bats in England and Scotland.

In North America, variants of rabies virus are maintained in the wild by several terrestrial carnivore species, including raccoons, skunks, and a number of bat species. Each antigenically and genetically distinct variant of the virus in mammalian species occurs in geographically discrete areas and is strongly associated with its reservoir species. Within each area, a spillover of rabies into other species occurs, especially during epidemics. Temporal and spatial analysis of skunk and raccoon rabies in the eastern United States, indicated that epidemics in raccoons and skunks moved in a similar direction from 1990 to 2000. However, to date there is no evidence that the raccoon rabies virus variant is cycling independently in the skunk population of the eastern United States or that the variant has undergone any genetic adaptations among skunks.

Within broad geographic regions, rabies infections in terrestrial mammals can be linked to distinct virus variants, identified by panels of monoclonal antibodies or by genetic analysis. These analyses have demonstrated substantial differences between isolates from various parts of the world. Most outbreaks of rabies tend to be host species-specific. Each variant is maintained primarily by intraspecific transmission within a dominant reservoir, although spillover infection of other species may occur within the region. Geographic boundaries of the currently recognized reservoirs for raccoons in terrestrial mammals have been established. Reservoirs for rabies virus are found worldwide. The virus is maintained at endemic and epidemic levels in a wide variety of Carnivora and Microchiroptera.
(bats) species. There are also antigenically similar rabies-like viruses, including the Makola virus, the Lagos bat virus, Duvenhage virus, European bat lyssavirus 1 and European bat lyssavirus 2 rabies, which are found principally in small mammals (rodents, insectivores, insectivorous or frugivorous bats). These strains appear to be limited in their geographical distribution to regions in Africa, unlike rabies virus which is distributed worldwide. The rabies-related viruses represent potential public and veterinary threats because of the lack of effective vaccines and the difficulties with diagnosis.

The geographic boundaries of the currently recognized reservoirs for rabies in terrestrial species in North America are as follows:

- Raccoons in the southeastern United States
- Red and arctic foxes in Alaska, resulting in spread across Canada as far east as Ontario, Quebec, and the New England states
- Striped skunks in California, the north central States, and the south central States
- Gray foxes in small reservoirs in Arizona
- Coyotes in south Texas as a result of spread from domestic dogs in a long-standing reservoir at the Texas-Mexico border.

The first reported occurrence of rabies in a human being infected with the raccoon rabies virus was from Virginia in 2002.14

In Ontario, wildlife rabies persists in two predominant species: the red fox and the striped skunk. Molecular epidemiology studies indicate that there is no host specificity, but rather there are very clear and consistent differences in the virus from distinct geographical regions. Such analyses will allow further epidemiological study of the behavior of the virus in different regions.

Overlying the disease in terrestrial mammals are multiple, independent reservoirs for rabies in several species of insectivorous bats. Distinct viral variants can be identified for different bat species, but geographical boundaries cannot be defined for rabies outbreaks in the highly mobile bat species.

Certain antigenic variants exist in nature against which conventional vaccines do not fully protect. In Canadian studies, two major antigenic groups can be distinguished among the rabies virus isolates examined. One group is found in Ontario, Quebec and the Northwest Territories and is represented in the wild by endemic red fox and striped skunk rabies that originated in northern Canada. The second group is found in Manitoba where striped skunk rabies is endemic.

The epidemiology of rabies in Chile and the animal species which serve as rabies reservoirs have been examined.22 None of Chilean isolates segregated with viruses from the terrestrial reservoirs. No non-rabies lyssaviruses were found, and the Chilean samples were not related to viruses of the sylvatic cycle maintained by the common vampire bat. The Brazilian free-tailed bat was identified as the reservoir for the rabies variant most frequently isolated in Chile from 1977 to 1998. The close association of a group of rabies viruses obtained from a domestic dog, Brazilian free-tailed bats, and a red bat with viruses maintained by red bat species in North America implicated species of this genus as the possible reservoirs of this particular genetic variant in Chile.

In Trinidad, bovine rabies is common and is due to the bat type.23

**Methods of transmission**

The source of infection is always an infected animal, and the method of spread is almost always by the bite of an infected animal, although contamination of skin wounds by fresh saliva may result in infection. Not all bites from rabid animals result in infection because the virus is not always present in the saliva and may not gain entrance to the wound if the saliva is wiped from the teeth by clothing or the coat of the animal. The virus may appear in the milk of affected animals, and spread by this means is unlikely as infection. The rabies virus is relatively fragile, susceptible to most standard disinfectants, and dies in dried saliva in a few hours.

One of the most important parameters in rabies models is the transmission rate, or the number of susceptible animals infected by a diseased animal per unit of time. In a population of 19 raccoons feeding at a concentrated, common food source available during the summer in rural eastern Ontario, raccoons bite and are bitten an average of 0.99 to 1.28 times per hour, respectively.24

Because of the natural occurrence of rabies in animals in caves inhabited by infected insectivorous bats, inhalation as a route of infection came under suspicion. It is now accepted that interbat spread, and spread from bats to other species is principally by bites, but that infection by inhalation also occurs. That infection can occur by ingestion has been put to use in devising systems of vaccinating wildlife by baiting them with virus-laden baits. This also has implications for epidemiological study generally. For example, attenuated viruses used in baits could be taken by other than the target species, thus creating an unexpected seropositive segment of the animal population. It is also considered likely that outbreaks occurring naturally amongst carnivores may originate by them eating bats that have died of rabies.

**Animal vectors**

Traditionally, the dog, and to a minor extent the cat, have been the main source animals. However, native fauna, including foxes, skunks, wolves, coyotes, vampire, insectivorous and fruit-eating bats, raccoons, mongooses, and squirrels provide the major source of infection in countries where domestic carnivora are well-controlled. In general, foxes are less dangerous than dogs, foxes tending to bite only one or two animals in a group, while dogs will often bite a large proportion of a herd or flock. Raccoons and skunks are major reservoirs of rabies in North America.

Bats are the important species in which subclinical carriers occur. Multiplication of the virus without infection of the nervous system is known to occur in fatty tissues in bats, and may be the basis of the 'reservoir' mechanism in this species. Violent behavior is rare in rabid animals of this species, but has been observed. Bats represent a serious threat of spread of rabies because of their migratory habits. Most spread is within the species, but the threat to humans and animal species by bats cannot be completely disregarded. Although rodents can be infected with the rabies virus they are not thought to play any part in the epidemiology of rabies, either as multipliers or simply as physical carriers of the virus. Many of the viruses they carry are rabies-like rather than classical rabies.

Rabies has occurred in swine herds where the skunk population is high, where farms were settled from rough terrain resulting in considerable interface between wildlife and domestic animals, and in which the management system allows the pigs to run free on the premises. The disease has occurred in pigs reared in a closed feeder barn where access by wildlife was very unlikely.

There is a difference in role between vectors. For example, in Europe it is thought that foxes carry the infection into a new area, but other species disseminate it within an area.25 Foxes are the principal vectors and, as in Canada, cattle are the principal receptors. In western Canada, the main reservoirs of infection are skunks, bats, and foxes. This would have important consequences for control programs based on wildlife surveillance.

Domestic livestock like cattle are rarely a source of infection, although chance
transmission to humans may occur if the mouth of a rabid animal is manipulated during treatment or examination. The virus may be present in the saliva for periods up to 5 days before signs are evident.

Seasonal spread

Spread of the disease is often seasonal, with the highest incidence in the late summer and autumn because of large-scale movements of wild animals at mating time and in pursuit of food. In Canada, the frequency of rabies infection in livestock populations increases in the fall when adolescent foxes mature, begin mating behavior, and travel over large areas.

Latent infection

Because of rapid developments in virological techniques, especially serological screening of animal populations to obtain presumptive diagnoses of the presence of a virus in the population, the question of latent infection and inapparent carriers of rabies has assumed some importance. The presence of rabies antibodies in animals in a supposed rabies-free area is likely to arouse concern. Inapparent carriers do occur in bats and there is some evidence that latent infections can occur in other species.

Zoonotic implications

The prime importance of rabies is its transmissibility to humans, with veterinarians being at special risk. European data indicate that by far the greatest proportion of humans requiring pre-treatment or rabies have been exposed to a rabid domestic animal, not a wild one.  

Human rabies is extremely rare in countries where canine rabies is controlled by regular vaccination. In the United States, a total of 28 cases of human rabies occurred from 1980 to 1995. Most were due to viral variants associated with bats. Rates of post-exposure prophylaxis in developing countries are about 10 times higher than those in the United States, and rates of human rabies are approximately 100 times higher. According to the WHO, over 30,000 people die each year from rabies and more than 10 million undergo post-exposure treatment, having been bitten by a rabid animal. In 1987, according to surveillance conducted by the World Health Organization, dogs were responsible for 91% of all human rabies cases; cats, 2%; other domestic animals, 3%; bats, 2%; foxes, 1%; and all other wild animals, fewer than 1%. The disease is a major occupational hazard for veterinarians who should receive pre-exposure prophylaxis. Because horses will bite each other and their handlers, rabid horses that are aggressive pose a serious threat to humans.

There is a lack of general rabies knowledge among the public. The laissez-faire attitude toward rabies by Americans causes instances of rabies exposure to be commonplace. A survey of middle school children in Texas found a lack of basic knowledge about rabies. Only 0.3% of children achieved a minimum score of 75% on a survey of knowledge about rabies. Respondents lacked knowledge about the disease is transmitted, and less than one-third were even aware of rabies epidemic in southern Texas despite the fact that a rabies epidemic had been occurring in southern Texas for the previous 13 years. Even more astonishing was the finding that 80% knew of the risk of acquiring rabies from an unvaccinated pet buy 57% claimed to own unvaccinated pets.

Rabies is not of major economic importance in farm animals, although individual herds and flocks may suffer many fatalities. The disease in humans has always been considered fatal. Since 1970, there have been reports of five patients said to have survived rabies encephalitis. All patients had received some rabies vaccine before the onset of clinical signs but none had had rabies immunoglobulin.

A 15-year-old girl who developed rabies one month after being bitten by a bat survived following intensive medical therapy including induced coma while a native immune response matured, and treatment with ketamine, midazolam, ribavirin, and amantadine. Probable drug-related toxic effects included hemolysis, pancreatitis, acidosis, and hepatotoxicity. The patient was discharged to her home after 76 days, and at nearly 5 months after her initial hospitalization she was alert and communicative, but with choreoathetosis, dysthria, and an unsteady gait.

Rabies in the Americas. Between 1993 and 2002, the number of human and canine rabies cases in the Americas Region fell by approximately 80%. There were 39 human cases in 2002, 63% of them transmitted by dogs. Human rabies transmitted by wildlife, mostly by bats is a risk to inhabitants in many countries in the Region. This sharp reduction is attributable mainly to the control measures implemented by the countries in the Region, such as mass vaccination of dogs and prophylactic treatment of people who have been exposed.

Economic importance

The economic costs of rabies in a country are associated with pet animal vaccinations, animal bite investigations, confinement and quarantine of domestic animals which bite humans or which are suspected of exposure to rabid animals, salaries of animal control officers, laboratory diagnosis, the costs of pre-exposure and post-exposure prophylaxis and treatment and consultation, public education, staff training and clerical costs.

The cost of the 'point infection control' program as a response to raccoon rabies introduction in Ontario in 1999 was $363,000 (Cdn) or $500 Cdn/km². The costs were justified as by containing the spread of raccoon rabies, annual savings to Ontario are estimated at $8 to 12 million. The reported associated costs in Ontario before raccoon rabies were estimated at about $6 million annually, excluding pet vaccination costs.

PATHOGENESIS

Following the deep introduction of rabies virus by the bite of a rabid animal, initial virus multiplication occurs in striated muscle cells at the site. The neuromuscular spindles then provide an important site of virus entry into the nervous system. Entry into the nervous system may also occur at motor end plates. In the olfactory end organ in the nares, neuroepithelial cells are in direct contact with the body surface and these cells extend without interruption into the olfactory bulb of the brain. Following entry of the virus into nerve findings, there is invasion of the brain by passive movement of the virus within axons, first into the spinal cord then into the brain. The immune response during this phase of the infection is minimal and explains why neutralizing antibody and inflammatory infiltration are usually absent at the time of onset of encephalitic signs. Antibody titers reach substantial levels only in the terminal stages of the disease. Following entry of rabies virus to the central nervous system (CNS), usually in the spinal cord, an ascending wave of neuronal infection and neuronal dysfunction occurs.

The primary lesions produced are in the CNS, and spread from the site of infection occurs only by way of the peripheral nerves. This method of spread accounts for the extremely variable incubation period, which varies to a large extent with the site of the bite. Bites on the head usually result in a shorter incubation period than bites on the extremities. The severity and the site of the lesions will govern to a large extent whether the clinical picture is primarily one of irritative or paralytic phenomena. The two extremes of the paralytic or dumb form and the furious form are accompanied by many cases that lie somewhere between the two. Gradually ascending paralysis of the hindquarters may be followed by
Viral diseases characterized by nervous signs

severe signs of mania, which persist almost until death. Destruction of spinal neurons results in paralysis, but when the virus invades the brain, irritation of higher centers produces manias, excitement, and convulsions. Death is usually due to respiratory paralysis. The clinical signs of salivation, indigestion and pica, paralysis of bladder and anus, and increased libido all suggest involvement of the autonomic nervous system, including endocrine glands. At death, there are viral inclusions and particles in almost all neurons in the brain, spinal cord and ganglia, but none in the supportive cells of the CNS. Electron microscopic examination also shows the presence of the virus in the cornea, which it reaches centrifugally along the peripheral nerves.

Virus reaches the salivary glands and many other organs in the same way, but the highly infective nature of saliva arises from passage of the virus along the olfactory nerve to taste buds and other sensory end organs in the oropharynx, rather than from the salivary glands. Experimentally, infection of non-nervous tissues in skunks and foxes has been reproduced in the adrenal medulla, cornea, and nasal glands. The virus may be found in milk, in some organs and in fetuses, but the virus cannot be demonstrated in the blood at any time.

Variations in the major manifestations as mania or paralysis may depend upon the source of the virus. Virus from vampire bats almost always causes the paralytic form-'fixed' virus that has been modified by serial intracerebral passage causes ascending paralysis in contrast to 'street' virus, which more commonly causes the furious form. The site of infection and the size of the inoculum may also influence the clinical course. There is also geographical difference in the proportion of animals affected by the furious or paralytic form of the disease. In the Americas most cases are paralytic. In Africa and India most cases in farm animals are the furious form.

The disease is always fatal, but infrequently an experimentally infected animal shows clinical signs of the disease but recovers. There are two recent records of spontaneous recovery in man, and the occurrence of non-fatal rabies in all species has been reviewed. There appears to be no field occurrence in domestic animals of the finding in experimentally infected mice that some strains of virus invade only peripheral nerves and spinal ganglia leaving a number of survivors with permanent nervous disability. The pathogenesis of recovery from rabies is important relative to vaccination and serological testing to determine the incidence and prevalence of the disease. The literature on the animal models used for the study of the pathogenesis and treatment of rabies has been reviewed. 1

**CLINICAL FINDINGS**

**Cattle and sheep**

**Cattle**

Among farm animals, cattle are most commonly affected. The incubation period in naturally occurring cases is about 3 weeks, but varies from 2 weeks to several months in most species, although incubation periods of 5 and 6 months have been observed in cattle and dogs. In one large-scale outbreak in sheep, deaths occurred 17–111 days after exposure.

Experimentally, in cattle the average incubation period was 15 days and the average course of the disease was 3.7 days. Unvaccinated cattle had shorter incubation and clinical duration of disease than vaccinated cattle. Major clinical findings included excessive salivation (100%), behavioral change (100%), muzzle tremors (80%), vocalization (bellowing 70%), aggression, hyperesthesia and/or hyperexcitability (70%), and pharyngeal paralysis (60%). The furious form occurred in 70%.

In sheep, experimentally, the average incubation period was 10 days, and the average course of the disease was 3.25 days. Major clinical findings included muzzle and head tremors (80%), aggressiveness, hyperexcitability and hyperesthesia (80%), trismus (60%), salivaition (60%), vocalization (60%), and recurrency (40%). The furious form occurred in 80% of sheep.

In the paralytic form, knuckling of the hind fetlocks, sagging and swaying of the hingquarter while walking, often deviation and flaccidity of the tail to one side, are common early signs. Decreased sensation usually accompanies this weakness and is one of the best diagnostic criteria in the detection of rabies. It is most evident over the hingquarters. Tenesmus, with paralysis of the anus, resulting in the sucking in and blowing out of air, usually occurs late in the inoculation stages just before the animal becomes recumbent. This is a characteristic finding but it may be transient or absent. Drooling of saliva is one of the most constant findings. The yawning movements are more accurately described as voiceless attempts to bellow. When paralysis occurs, the animal becomes recumbent and unable to rise. Bulls in this stage often have paralysis of the penis. Death usually occurs 48 hours after recurrency develops and after a total course of 6–7 days. The paralytic form of rabies has been reproduced experimentally by the IM injection of brain tissue from naturally occurring cases of paralytic rabies ('derriengue') in cattle in Mexico.

In **furious rabies** the animal has a tense, alert appearance, is hypersensitive to sounds and movement, and is attracted to noise so that it may look intently or approach as though about to attack. In some cases, it will violently attack other animals or inanimate objects. These attacks are often badly directed and are impeded by the incoordination of gait. Frequently, loud bellowing is usual at this stage. The sound is characteristically hoarse and the actions are exaggerated. Sexual excitement is also common, bulls often attempting to mount inanimate objects. Multiple collections of semen for artificial insemination have been made during very short periods from bulls that later proved to be rabid. With this violent form of the disease the termination is characteristically sudden. Severe signs may be evident for 24–48 hours and the animal then collapses suddenly in a paralyzed state, dying usually within a few hours.

There is no consistent pattern in either the development or the range of signs. Body temperatures are usually normal but may be elevated to 39.5–40.5°C (103–105°F) in the early stages by muscular activity. Appetite varies also. Some animals do not eat or drink, although they may take food into the mouth. There is apparent inability to swallow. Others eat normally until the terminal stages. The course may vary from 1 to 6 days. So wide is the variation in clinical findings that any animal known to be exposed and showing signs of spinal cord or brain involvement should be considered rabid until proved otherwise.

**Sheep**

In sheep, rabies often occurs in a number of animals at one time due to the ease with which a number of sheep can be bitten by a dog or fox. Clinically, the picture is similar to that seen in cattle. The minority show sexual excitement, attacking humans or each other, and vigorous wool pulling; sudden falling after violent exertion, muscle tremor, and salivation are characteristic. Excessive bleating does not occur. Most sheep are quiet and anorectic. Goats are commonly aggressive and, continuous bleating is common.

**Horses**

Most recorded cases in horses are lacking in distinctive nervous signs initially, but incline to the paralytic form of the disease. Experimentally, the average incubation period was 12 days and the average duration of disease was 5.5 days. Unvaccinated animals had shorter incubation periods and duration of clinical disease. Muzzle tremors were the most frequently observed and most common initial signs. Other clinical findings
Lameness or weakness in one leg may be the dumb form. The paralytic form occurred in 43% of cases, some of which began as the dumb form. The paralytic form was not observed.

In naturally occurring cases, the initial clinical findings may include abnormal postures, frequent whinnying, unexplained aggressiveness and kicking, biting, colic, sudden onset of lameness in one limb followed by recumbency the next day, high-stepping gait, ataxia, apparent blindness, and violent head-tossing. Lameness or weakness in one leg may be the first sign observed, but the usual pattern of development starts with lassitude, then passes to sternal recumbency and lateral recumbency, followed by paddling convulsions and terminal paralysis.

In a series of 21 confirmed cases in horses, the clinical findings at the time of initial examination included ataxia and paresis of the hindquarters (43%), lameness (24%), recumbency (14%), pharyngeal paralysis (10%), and colic (10%). The major clinical findings observed over the course of hospitalization included recumbency (100%), hyperesthesia (81%), loss of tail and anal sphincter tone (57%), fever of 38.5°C (52%), and ataxia and paresis of the hindquarters (52%). Mean survival time after the onset of clinical signs was 4.47 days (range, 1–7 days). Clinical findings of the furious form of rabies, such as aggressiveness (biting), compulsive circling, and abnormal vocalization, were evident in only two horses. Supportive therapy, given to nine horses, had no effect on survival time and did not correlate with the detection of Negri bodies at necropsy. Horses developing the furious form show excitement, become vicious, and bite and kick. Their uncontrolled actions are often violent and dangerous and include blind changes, sudden falling and rolling and chewing of foreign material or their own skin. Hyperesthesia and muscular twitching of the hindlimbs followed by crouching and weakness are also recorded in the horse.

CLINICAL PATHOLOGY

No antemortem laboratory examination is of diagnostic value, but tests for lead on blood, urine, and feces may help to eliminate lead poisoning as a possible cause. Virus neutralization tests are available, but the presence of antibodies is not diagnostic. Other available tests are passive hemagglutination, complement fixation, radioimmunoassay, and indirect fluorescent antibody staining. These are used to determine immune status rather than as a diagnostic aid. An ELISA is available for measurement of rabies-specific antibody in the sera of major domestic and wildlife reservoirs in North America.

NECROPSY FINDINGS

Confirmation of a diagnosis of rabies depends on careful laboratory examination of fresh brain. The recommended laboratory procedure includes the following three tests and it is recommended that at least two of them be used on all specimens.

- A fluorescent antibody test (FAT) on impression smears from the brain – current recommendations include sampling of the hippocampus, medulla oblongata, cerebellum or gasserian ganglion. However, a recent publication stipulates that the hippocampus and cerebellum are less desirable samples than the thalamus, pons, or medulla for the detection of viral antigen, and that the current sampling recommendations stem from the visibility of Negri bodies, rather than the true distribution of viral antigen. An FAT can be completed in approximately 2 hours and is highly accurate when done routinely by experienced personnel. The reliability of FAT confirmed by the mouse inoculation test is over 99%. Those specimens that are negative on FAT, and have contact with humans, are inoculated into experimental mice. The incubation period in mice before clinical signs are seen averages 11–12 days (range of 4–18 days), and death occurs in 7–21 days. The mouse brain is harvested as soon as signs appear and is submitted to the same tests described above. Thus a positive result can be obtained as soon as 4–7 days after inoculation. Some mice must be kept for the full 21 days because only a negative result at that time can give a complete negative to the test. A tissue culture infection test is now available, which allows demonstration of the virus in stained tissue culture cells within 4 days. This may replace the mouse inoculation test.

- A dot ELISA is available for the detection of rabies antigen in animals. It is rapid, simple, economical and, in comparison with the FAT, the agreement is 95%.

A histological search for Negri bodies in tissue sections with results available in 48 hours. Because of false-positive diagnoses the technique is in some disrepute. An immunoperoxidase test for rabies can be used on formalin-fixed, paraffin-embedded brain tissues of domestic animals and wild animals when fresh tissues are not available. In some cases, the brain tissue may be negative for the rabies virus using standard diagnostic techniques but immunohistochemical tests may detect the presence of antigen.

A reverse transcriptase polymerase chain reaction test has been found of value in detecting rabies infection in decomposed brain samples that were negative by the direct fluorescent antibody test.

The histopathologic changes of rabies infection include a non-suppurative encephalomyelitis and ganglioneuritis, with neuronal necrosis and the formation of glial nodules. Negri bodies are most commonly found in the Purkinje cells of the cerebellum in ruminants. Spongiform change has also been reported in the brain of a heifer infected with rabies virus.

Samples for confirmation of diagnosis

- Histology – half of midsagittally-sectioned brain, cervical spinal cord (including root ganglia), gasserian ganglion, parotid salivary gland (LM, IHC)
- Virology – half of midsagittally-sectioned brain, cervical spinal cord (FAT, ISO, BIOASSAY)

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

Differential diagnosis

The diagnosis of rabies is one of the most difficult and important duties that a veterinarian is called upon to perform. Since in most cases there is a probability of human exposure, failure to recognize the disease may place human life in jeopardy. It is not even sufficient to say that if rabies occurs in the area one will classify every animal showing nervous signs as rabid, because nervous signs may not be evident for some days after the illness commences. In addition, many animals suffering from other diseases will be left untreated. The best policy is to handle all suspect animals with extreme care but continue to treat them for other diseases if such treatment appears to be indicated. If the animal is rabid, it will die and the diagnosis can then be confirmed by laboratory examination.
Several diseases are characterized by signs of abnormal mental state or paralysis, or a combination of both (see Table 22.1 for the horse; Table 32.3 for cattle). Rabies must be differentiated from the following common diseases affecting the nervous system, according to species:

**Cattle and sheep**
- Lead poisoning. In acute and subacute lead poisoning in cattle the clinical findings are similar to those of furious and dumb rabies. In acute lead poisoning, the common clinical findings are blindness, convulsions, champing of the jaws with the production of frothy saliva, twitching of the eyelids and ears. In subacute lead poisoning in cattle there is blindness, stupor, head-pressing, grinding of the teeth, and almost no response to treatment. Rabid cattle are usually not blind, and signs of motor irritation such as convulsions and twitching of the facial muscles usually do not occur. However, there are signs of bizarre mental behavior, such as wild gazing, bellowing, yawning, attacking, and compulsive walking.
- Lactation tetany occurs in lactating cattle on lush pasture in the spring during cold wet and windy weather, and is characterized by hyperesthesia, tremors, convulsions, recumbency, and rapid death.
- Vitamin A deficiency occurs in groups of young cattle from 6 months to 18 months of age not receiving adequate carotene intake or vitamin A supplementation and is characterized by blindness in the ocular form and episodes of tremors and convulsions.
- Polioencephalomalacia in cattle and sheep is characterized by blindness, nystagmus, opisthotonic, and convulsions; bellowing, loss of sensation, and tenesmus do not occur.
- Listeriosis in cattle and sheep is manifested by localizing signs of circling and facial nerve paralysis.
- Enterotoxemia in sheep is usually confined to lambs on heavy carbohydrate diets.
- Pregnancy toxaemia is a disease of pregnant ewes and is readily differentiated by the presence of ketonuria.
- Louping-ill in sheep is transmitted by insects, has a seasonal occurrence, and a localized geographical distribution.

**Pigs**
In pigs, rabies must be differentiated from pseudorabies, Teschen's disease, and involvement of the brain in several other diseases of the pigs, such as hog and African swine fever, meningitis associated with Streptococcus suis type II, Haemophilus spp., Glasser's disease, Eschericha coli, septicaemia, and erysipelas.

**Horses**
In horses, rabies must be differentiated from several diseases of the nervous system (summarized in Table 22).

The most common include: viral encephalomyelitis, herpes virus myeloencephalopathy, cerebrospinal nematodiasis, equine degenerative myeloencephalopathy, equine protozoal myeloencephalitis, neuritis of the cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism.

**TREATMENT**
No treatment should be attempted after clinical signs are evident. If the bite is seen, immediately after exposure, irrigation of the wound with 20% soft soap solution or a solution of Zephiran may prevent the establishment of the infection. Immediate and thorough washing of all bite wounds and scratches with soap and water is perhaps the most effective measure for preventing rabies in veterinarians bitten by rabid animals. In experimental animals, simple local wound cleansing has been shown to markedly reduce the likelihood of rabies. Post-exposure vaccination is unlikely to be of value in animals, as death usually occurs before appreciable immunity has had time to develop. Euthanasia of suspect animals must be avoided, particularly if human exposure has occurred, since the development of the disease in the animals is necessary to establish a diagnosis. Antirabies serum may become available for animal treatment at some future date. In some countries, cases of rabies in farm animals are notifiable to the animal health and disease regulatory bodies.

**CONTROL**
The major goal of rabies control in domestic and wild animals is the reduction or elimination of human rabies. The most rational approach to reducing human rabies is to reduce the prevalence and incidence of disease in animals. In developed countries, this has been accomplished by vaccination of dogs and cats, leaving much rabies in wildlife to be controlled. In countries without wildlife reservoirs, such as the Philippines, it would be economically advantageous to eliminate dog rabies. In Africa, where the incidence of rabies as well as the range of species involved is increasing, there is a need to develop new and economical methods of vaccinating domestic animals.

Pre-exposure immunization for individuals, like veterinarians, who are at high risk to rabies, has been recommended by the World Health Organization, since it reduces risk and provides a more rapid anamnestic response, eliminating the need for human globulin should exposure occur. Rabies pre-exposure vaccination is now mandatory in many veterinary colleges. Despite some mild adverse reactions, immunization against rabies is an important prophylaxis measure well-accepted by veterinary students.

For farm animals, there are two useful control techniques: the prevention of exposure and pre-exposure vaccination.

**Prevention of exposure to the virus**
This can be achieved by controlling access of wildlife species which are likely to come into contact with the farm livestock in particular areas or through vaccination of the wildlife. Foxes accounted for a very large proportion (85% in Europe) of wildlife rabies, and a control program aimed at reducing their population using poison or traps was attempted until the 1970s. This method of population reduction failed to control outbreaks or reduce enzootic rabies.

**Point infection control.** To control the introduction of raccoon rabies in Ontario in 1999, ‘point infection control’ was used to control the epidemic. This involves the use of three tactics: population reduction, trap-vaccinate-release, and oral vaccination with baits to control the spread of raccoon rabies. Some raccoons were captured and euthanized which resulted in an 83 to 91% reduction in the raccoon population in an area of 225 km² around the location of the three original cases of raccoon rabies. Raccoon density in the population reduction zones declined from 5.1 to 7.1 km² to 0.6 to 1.1 km² following control. Cats were also captured, vaccinated and released. Raboral V-RG oral rabies vaccine was distributed aerially to vaccinate free ranging raccoons. The point infection control program is considered to be highly successful and will continue to be used to contain isolated cases of raccoon rabies.29

**Pre-exposure vaccination of humans**
The most successful form of rabies prevention is pre-exposure vaccination. In human medicine, there are no reported cases of rabies deaths in anyone who has had pre-exposure vaccination followed by a booster vaccination if exposed.4

The Centers for Disease Control (CDC) and Prevention has published the recommendations of the Advisory Committee on Immunization Practices (ACIP) for human rabies prevention, which indicate that rabies pre-exposure vaccination should be offered to persons more likely to be exposed to rabies virus than the population of the United States at large. The recommendations of the ACIP for pre-exposure prophylaxis and maintenance of a detectable antibody titer differ depending on the estimated degree of risk of exposure to the virus. Four risk categories have established: continuous; frequent; infrequent; and rare. The classification depends on factors such as the occupation of the individual and geography.

With directed continuing education, common sense, first aid, and the availability of modern biological agents, human rabies is nearly always preventable.1 Rabies pre-exposure vaccination is recommended for anyone at increased risk of exposure to rabies, including veterinarians, veterinary students who...
work in university veterinary teaching hospitals, laboratory staff working with rabies, vaccine producers, animal and wildlife control personnel, and zoologists.

The standard pre-exposure regimen is three doses of vaccine IM or ID on days 0, 7, and 28 (or 21). A booster dose after 1 year increases and prolongs the antibody response. This pre-exposure vaccination permits post-exposure vaccination to consist of two doses of vaccine on days 0 and 3 instead of 5 on days 0, 3, 7, 14, and 28 and avoids the need for postexposure of administration of human rabies immunoglobulin.

A large proportion of at-risk staff members working in veterinary clinics, animal shelters, and wildlife rehabilitation centers in a study area did not receive rabies pre-exposure vaccination according to the recommendations of the ACIP of the CDC.\(^4\)\(^7\)\(^8\)\(^9\) Cost may be factor because many of these employees are commonly short-term, part-time, or volunteer workers.

**Post-exposure vaccination of humans**

Modern post-exposure treatment is highly successful if done adequately. Wound care with passive and active rabies immunization are essential especially after severe exposure. Post-exposure treatment is assumed to neutralize or inactivate virus while it is still in the wounds, before it gains access to the nervous system where it is protected from the immune system. Therefore, treatment after exposure to rabies virus is very urgent, even if the patient was bitten months before. Thorough washing of rabies-infected wounds with soap and water can increase survival by 50\%. However, this inexpensive, readily available treatment is omitted in most cases.

The World Health Organization recommends a multi-site intradermal regimen of 0.1 mL of vaccine at eight sites on day 0, at four sites on day 7, and at one site each on days 28 and 90.\(^9\)\(^9\)

Passive immunization with human rabies immunoglobulin lowers mortality after severe exposure.

**Post-exposure vaccination of domestic animals**

An effective post-exposure protocol for unvaccinated domestic animals exposed to rabies includes immediate vaccination against rabies, a strict isolation period of 90 days, and administration of booster vaccinations during the third and eighth weeks of the isolation period.\(^0\)\(^0\) The protocol has been effective in dogs, cats, cattle, and horses.

**Vaccination of domestic animals**

A *Compendium of Animal Rabies Control* is published annually by the National Association of State Public Health Veterinarians, Inc. in the United States and Canada.\(^2\)\(^5\)\(^8\)\(^9\) It provides recommendations for immunization procedures in domestic animals, the vaccines licensed and marketed in the United States. Detailed information is provided on pre-exposure vaccination, management of dogs and cats and livestock, post-exposure management, and control methods in wild animals. Such publications should be consulted when necessary. In general, for cattle, sheep, and horses the primary vaccination is given at 3 months of age and boosters given annually. Farm livestock in endemic areas where clinical cases of rabies occur commonly should be vaccinated.

In countries where vampire bats are a major vector for rabies in farm livestock, vaccination of livestock is necessary but in countries such as Argentina, vaccination does not support a cost benefit analysis.\(^4\)\(^1\)

**Vaccines**

Almost all rabies vaccines for domestic animals are inactivated.\(^2\)\(^5\) Inactivated tissue culture cell vaccines given to cattle result in neutralizing antibodies in 1 month after the primary vaccination. A booster given 1 year later increases the titers, which are detectable 1 year after the booster. A vaccine inactivated with binary-ethyleneimine, and containing aluminum hydroxide adjuvant, provides excellent protection for up to 3 years and is very useful for the control of rabies in cattle in Latin America where the vampire bat is the main vector.

Vaccinal antibodies are present in the colostrum of vaccinated cows and it is recommended that, where cattle are vaccinated annually, calves be vaccinated at 4 months of age and again when 10 months of age. Calves from unvaccinated dams can be protected by vaccinating them at 17 days of age. Postvaccinal paralysis does not occur after its use.

A post-exposure vaccination protocol including immediate rabies vaccination, with a minimum of one booster vaccination prior to release from quarantine, and 90 days strict isolation, was 99.7% successful in unvaccinated cattle, horses, sheep, goats, and pigs.

**Vaccination of wildlife**

The literature on oral rabies vaccination of wild carnivores in the United States has been reviewed.\(^6\) Mass oral vaccination of terrestrial wild animals is a rabies control method that is feasible, effective, and internationally accepted.\(^3\)\(^6\)\(^7\)\(^8\)\(^9\)\(^2\) It is based on the concept of applied herd immunity. The vaccines are efficacious when fed as vaccine-baits. The factors affecting acceptance of baits for delivery of oral rabies vaccine to raccoons have been examined.\(^4\)\(^4\)

The oral immunization of foxes has resulted in a substantial decrease in the number of rabies cases in Europe. As a result of oral vaccination of the red fox (*Vulpes vulpes*) against rabies, using hand and aerial distribution of vaccine-laden baits, the rabies virus has almost been completely eradicated from Western and Central Europe.\(^4\)\(^5\) The same dramatic decrease occurred in southern Ontario, Canada. In most countries, vaccine baits were distributed twice yearly; during the spring (March to May) and autumn (September to October). Several European countries have become rabies-free: Belgium, Luxembourg, France, Italy, Switzerland, Finland and the Netherlands.\(^4\)\(^3\)

With the European Union consisting of 25 countries from May 2004, all the scientific knowledge is available for establishing efficient and adapted oral vaccination programs aimed at eliminating terrestrial raccoons from this area.

Progress has been made in applying oral rabies vaccination to contain and eliminate some strains of terrestrial raccoons in North America.\(^4\)\(^2\) Notable examples include near elimination of rabies from red foxes in southern Ontario. Containment and elimination of canine rabies coyotes from south Texas, containment and near elimination of raccoon rabies from Ohio, prevention of raccoon rabies spread through the Lake Champlain Valley in New York and across northern Vermont and New Hampshire, and reduced incidence of rabies where other oral rabies vaccination projects targeting raccoons have occurred. As of 2005, both Ontario and New Brunswick were free of raccoon rabies for greater than 10 months and 2 years, respectively, after implementation of ‘point infection control strategies’\(^2\)\(^9\) but continued surveillance is critical to monitor effectiveness.

Raboral V-RG is the only rabies vaccine licensed for use in the United States. It has not produced sufficient levels of population immunity in skunks in the wild at the current dose and V-RG may be less effective in skunks than other species. Skunks are a major contributor to rabies in North America with 38% of cases associated with the raccoon variant of rabies virus involved skunks in 2001.\(^1\)\(^2\) This has raised concerns about an independent maintenance cycle for raccoon rabies in skunks. The national rabies management goals of virus containment and elimination of will likely remain elusive until an oral vaccine is licensed that is immunogenic in all terrestrial raccoon reservoir species. Skunk rabies virus, which has the broadest geographic distribution of all terrestrial raccoon variants in the USA can currently be addressed only through local trap-
vaccine-release or population suppression programs. The vaccination will succeed in reducing or eradicating rabies only if a sufficient proportion of the target population can be immunized. Mathematical modeling techniques are now being tested to examine the population biology of rabies in wildlife species such as raccoons and skunks.43 Mass immunization of foxes by aerial distribution of vaccine-baits containing liquid rabies vaccine was highly successful in controlling rabies in both urban and rural areas of Ontario. In 1989, the Ontario program began a 5-year experiment to eliminate terrestrial rabies from a study area in the eastern end of southern Ontario.44 Baits containing oral rabies vaccine were dropped annually in the area at a density of 20 baits/km² from 1989 to 1995. The experiment was successful in eliminating the arctic fox variant of rabies from the entire area. In the 1980s, an average of 235 rabid foxes per year were reported in the study area. Between 1993 and 2001, no cases were reported. Cases of fox rabies in other species also disappeared. In 1995, the last bovine and companion animal cases were reported and in 1996 the last rabid skunk occurred. Only bat variants of rabies were present until 1999, when the raccoon variant entered from New York.

**Quarantine and biosecurity**

The most effective method of preventing the entry of rabies into a country free of the disease is the imposition of a quarantine period of 4–6 months on all imported dogs. This system has successfully prevented the entry of the disease into island countries, but has obvious limitation in countries that have land borders. The occurrence of the disease in two dogs in the United Kingdom in 1969–1970 in which the incubation period appeared to last 7–9 months suggests that the more usual period of 6 months may give incomplete protection. Therefore, vaccination on two occasions with an inactivated vaccine while the animal is still in quarantine for 6 months is the current recommendation. To require a longer period of quarantine would encourage evasion of the law by smuggling. The situation in the United Kingdom, and in any country where the disease does not occur, is a vexed one. It is possible to rely chiefly on quarantine and act swiftly to stamp the disease out if it occurs. The shock eradication program would include quarantine of, and vaccination in, a risk area, ring vaccination around it, and destruction of all wildlife. This procedure is likely to be adopted in countries where the risk is small, such as Australia. Where the risk is great, consideration must be given to mass vaccination of wildlife by baits, because wildlife are the cracks in the defense armor. The use of combined vaccines containing rabies vaccine in other vaccines used in dogs would be an effective and panic-free way of increasing the immune status of the pet population.

**REFERENCES**

ETIOLOGY
Pseudorabies is associated with porcine herpesvirus-1, Aujeszky's disease virus, or pseudorabies virus, a member of the family of Herpesviridae, subfamily Alphaherpesvirinae. The biological functions of the virus in the pathogenicity, immunogenicity, and transmission of vaccine strains of the virus in pigs have been described and reviewed.1

EPIDEMIOLOGY
Occurrence
Pseudorabies primarily affects pigs and occurs incidentally in other species. Pseudorabies had a wide geographical distribution including the United States, Britain, Europe, North Africa, Asia, South America, New Zealand, and Ireland. Recently, many countries have achieved freedom from the disease and those that have not have started some form of control and eradication scheme.

Epidemiological modeling of the herd-to-herd transmission of pseudorabies over a 20-year period in the United States concluded that, if there is no eradication program in place, the projected prevalence would be 43% in high-risk States, 22% in moderate-risk States, and 5% in low-risk States by 2012.2 The current program of eradication projected 23% prevalence rate in high-risk States, 10% in moderate-risk States, and 1% in low-risk States. With an increase in expenditure for eradication programs of 25%, the respective prevalence rates by 2012 would be 14%, 3% and <0.3%. In Belgium the overall herd prevalence was deemed to be 35%.3 Many countries including Australia, Canada, and Norway are free of the infection.

Pseudorabies is primarily a disease of pigs, and naturally occurring cases in cattle and horses are rare and usually fatal. Cases in cattle occur only sporadically but a number of animals may be affected when cattle and pigs are commingled. An outbreak of clinical disease occurred in sheep in Northern Ireland after the sheep had been shown and housed adjacent to pigs excreting the virus4; cats on the same farm were also affected. The disease has occurred in goats that have been housed with swine, and the virus has been isolated from horses with neurological disease.5 Pseudorabies infection has been recorded in feral swine in Florida, and may undermine eradication efforts in domestic swine.6

Morbidity and case fatality
Typically, the disease spreads rapidly in infected herds over a period of 1–2 weeks and the acute stage of the outbreak lasts 1–2 months. In sucking pigs, the morbidity and mortality rates approach 100%, but in mature swine there may be no clinical signs, and affected animals usually recover. The highest morbidity occurs initially in unweaned piglets, but as the outbreak continues and piglets become passively immunized through the sow’s colostrum, the major incidence may occur in weanlings.

In recent years there has also been an increase in the morbidity and case fatality rates in older pigs associated with the intensification of pig rearing and the dominance of more virulent strains.

Risk factors
Animal risk factors
The seroprevalence of infection varies widely between herds, and between breeding and finishing pigs within herds.7 The most important animal risk factors of virus persistence are herd size and the population density of the sows in the herd.8 Endemic infection is more likely in herds of breeding sows with more than 66 sows. In Belgium, when testing 720 herds, 40% of the herds with young sows were highly positive.9 Herds over 70 sows were also more likely to be infected.2 In breeding herds, spread of infection is positively associated with increasing size of the herd, having the gilts in the same barn as the sows (gestation barn), and serological evidence of infection in the finishing pigs.9 The seroprevalence of infection is low in quarantined breeding herds, which makes them prime candidates for elimination of the disease by test and removal.10

In the early period of a compulsory vaccination program with gl-deleted vaccines, in an area endemically infected with the disease, the seroprevalence of infected breeding females is higher in farrow–finish than farrow–feeder herds.11

Mandatory vaccination is beneficial in both herds but the pattern is linear in farrow–feeder herds and curvilinear in farrow–finish herds, being more rapid in the early period of the program. In the farrow–finish herds, the odds of infected breeding females were associated positively with seropositivity in the finishing pigs of the herd and with the density of the pigs in the county in which the herd is located.13

In Belgium the presence of finishing pigs in the same herd increased the chances of being infected. The spread and transmission of the virus between herds can be reduced by a reduction in the contact rate between the herds and their size and by a reduction of the transmission within the herd.

The factors associated with circulation of the virus within herds include:
- Confinement of finishing pigs
- Concurrent infection with *Actinobacillus pleuropneumoniae*
- The length of time since the herd has been under quarantine
- The presence of clinical disease.

In general, pseudorabies does not increase the susceptibility of animals to infection with other pathogens. In an experimental situation it has been shown that the virus is transmitted between vaccinated conventional pigs but not amongst vaccinated SPF pigs.

The primary risk factors associated with seroprevalence of the virus in 500 swine herds in Illinois included total confinement and density of infected herds in the geographical area. For counties with a high regional density of pseudorabies infection, the prevalence of infection within a county increased with increasing average herd size and increasing geographical density of swine herds in the county. In Minnesota, there was a high geographical density of pseudorabies infected herds within 5 km. Similarly it was calculated in Belgium if there were over 455 pigs/km² then there was a 10-fold increase in the risk of PRV. Total confinement is associated with higher seroprevalence, presumably because of increased density of population and increased risk of transmission. In Pennsylvania, decreased density of pseudorabies-quarantined herds was associated with reduced risk of a herd becoming quarantine, whereas increased density of non-quarantined, uninfected herds was associated with a decreased probability of a herd becoming quarantined. A farrow-finish herd was associated with increased probability of becoming quarantined, compared with being a feeder pig herd. Seroprevalence is higher in vaccinated herds, increases over the course of the eradication program, and decreases with an increased time between quarantine and the development of a herd plan.

In The Netherlands, the risk factors contributing to seroprevalence of infection in breeding herds included:
- Presence of finishing pigs
- Production type (producers of finishing pigs had a higher prevalence than producers of breeding stock)
- Vaccination of sows during nursing (in comparison to vaccinating all sows simultaneously at 5-month intervals, or vaccination during the second half of gestation)
- Pig density in the municipality where the herd was located (seroprevalence increased with higher pig density)
- Herd size of fewer than 100 sows
- Average within-herd parity (seroprevalence increased with higher within-herd parity)
- Replacement pigs raised on the premises
- Vaccine strain administered to the sows.

Environmental risk factors
The survival capabilities of the virus under various environmental conditions influences the methods of transmission and control procedures. The virus may survive for 2–7 weeks in an infected environment, dependent on temperature fluctuations and pH level, and for up to 5 weeks in meat. The stability of the virus suspended in aerosol under different conditions of temperature and relative humidity has been examined. The infectivity of the virus in an aerosol decreases by 50% in 1 hour. Environments at 4°C supported the survival of the virus in aerosol better than at 22°C. The virus is lipophilic and sensitive to several commonly used disinfectants. Sodium hypochlorite (5.25%) is the most desirable and practical disinfectant. Suspensions of the virus in saline G solution and on the solid fomites, whole corn, and steel remained infectious for at least 7 days. Loam soil, straw, and concrete supported survival of the virus at 25°C for up to 1 week. During shipment of pigs, bedding material and surfaces in contact with pigs may become contaminated. Rinsing a needle between sampling may reduce the probability of mechanically transmitting the disease.

Pathogen factors
Field strains of the virus differ in virulence. Numerous genomically different strains of the virus exist, and restriction endonuclease (RE) analysis can distinguish between virus isolates, which is useful for identifying new isolates of the virus as they appear in pig populations. A retrospective analysis of virus isolates from England and Wales over a 22-year period revealed considerable homogeneity of certain RE sites (BamHI), both in number and size. The appearance of an isolate with a new DNA fragment in 1981 coincided with a marked increase in the number of outbreaks of disease. A PCR assay was able to discriminate between the established strains and the new type. By relating this type to pig movement records it was possible to trace the spread of the new type virus which was isolated in 65% of the new outbreaks of pseudorabies in England and Wales in 1982. In Denmark, restriction fragment analyses of older clinical isolates, and of isolates from all the virologically confirmed outbreaks since 1985, indicated the introduction of foreign strains. Strain variation in virulence has been observed in field isolates and produced by laboratory attenuation. The viral proteins that determine virulence of the virus have been described. Some field strains of the virus from Poland and Hungary have been identified by restriction fragment pattern analysis as derivatives of conventionally attenuated vaccine strains. This is considered a rare event but must be considered in relation to trade in semen from vaccinated boars or trade in live animals between disease-free areas and areas where vaccination with live attenuated strains is practiced.

Methods of transmission
Pigs, and possibly rodents, appear to be the primary host for the virus. The virus is present in the nasal discharge and in the mouth of affected pigs on the first day of illness and for up to 17 days after infection.

Within herds
Transmission within herds occurs by direct oral–nasal contact between infected and susceptible pigs, and aerosols from projection of discharges during sneezing, but may also occur via contaminated drinking water and feed. Transmission within herds is independent of the size of the population.

The spread of virus from infected animals to contact-exposed animals can be predicted using a reproduction ratio. The ratio of secondary cases to originally infected animals is called the basic reproduction ratio denoted as $R_0$. In the model, $R_0$ has a threshold property. When $R_0 > 1$, the infection can spread; when $R_0 < 1$, the infection will not spread and will disappear, and the animal population is effectively protected. Experimentally, the quantification of vaccine-induced reduction in virus transmission indicates that vaccinating twice with a marker vaccine significantly reduced virus transmission. In unvaccinated groups, the $R_0$ was 10.0; in the vaccinated group the $R_0$ was 0.5. Thus, it is possible to measure transmission experimentally.

The transmission of virus decreases rapidly following the start of a vaccination program but extensive spread can still occur even among finishing pigs vaccinated twice. Vaccinated pigs may shed more virulent virus than mildly virulent virus.
but there are no significant differences in magnitude of transmission.\textsuperscript{29} Mixing of chronically infected pigs with seronegative pigs may not result in seroconversion in the seronegative pigs until a clinical outbreak of disease occurs.\textsuperscript{30}

Between herds

Transmission between herds is due to introduction of infected animals, and the virus may still be introduced into vaccinated breeding herds.\textsuperscript{31} Other methods of transmission of the virus into uninfected herds have been suggested, including farm laborers, vehicles, feed-stuffs, rodents, and wild or domestic animals.

Within an area

Transmission within an area is a major problem and not well-understood. Spread is occurring across the United States despite an intensive eradication program.\textsuperscript{16} Some evidence indicates that area spread may be associated with which swine market is used and the frequency of delivery of pigs to market per year.\textsuperscript{2} In France it has been suggested that the presence of an infected herd within 1 km is an important factor in the spread of PRV.\textsuperscript{32} The concurrent occurrence of an outbreak of disease on many farms in the same area in Denmark suggested long-distance airborne transmission of the virus.\textsuperscript{33}

Infection is spread by airborne transmission.\textsuperscript{34} Exposing pigs to aerosols of the virus results in respiratory and other clinical signs similar to field cases.\textsuperscript{35} Sneezing probably generates the airborne virus. In a series of outbreaks in Britain between 1981–1982, seven of 11 were found to be likely to have been transmitted by aerosol on meteorological grounds.\textsuperscript{36} Airborne spread occurred between herds 2–9 km apart. An epidemic in Denmark in 1987–1988, associated with foreign strains of the virus, suggests that airborne transmission occurred across the German–Danish border\textsuperscript{37} especially as a southerly wind was blowing during the period of transmission. An epidemic occurred in 10 herds located within close proximity of each other in Indiana, and the clinical and meteorological data supported aerosol transmission of the virus.\textsuperscript{38} An epidemic during the winter of 1987/88 was associated with an unusual predominance of southerly winds, supporting the hypothesis of airborne transmission of the disease.\textsuperscript{39}

Computer modeling based on the mean dose of virus received by an animal at a farm downwind can be used to predict the airborne spread of the virus.\textsuperscript{38} To test the hypothesis that the virus can be spread by aerosol, the application of a Gaussian diffusion model has been applied to an epidemic of pseudorabies in 10 herds located in Indiana.\textsuperscript{39} The epidemic spread through 10 farms across an area of 150 km. The county was free of infected herds for 2 years prior to the epidemic, which was well-documented. The transport of the virus was assumed to occur during the prepatent period from 3 to 7 days prior to the onset of clinical signs. Estimates of the virus dose received at a given barn indicate that transport of the virus was more efficient during the night than during the day. The low temperatures during the night resulted in decreased ventilation of the barn and greater cycling of air contaminated with the virus over the pigs.

The infection is transmitted in feral swine through the venereal route.\textsuperscript{40} Following commingling of uninfected gilts with virus infected boars, the virus could be recovered from the reproductive tracts of the gilts and could not be recovered from the upper respiratory tract.

Virus is excreted in the milk of infected sows and in utero infection occurs. The virus is inactivated in meat after 35 days of storage at \(-18^\circ\mathrm{C}\) (0.5°F). Meat from infected pigs may cause infection when fed to dogs. Venereal transmission of latent infection in sows and boars has been suspected, but there is no direct evidence. The effects of pseudorabies infection in adult boars are related to the effects of the clinical disease rather than any direct effect on semen quality. The virus cannot usually be isolated from the urine or semen from infected boars, and therefore the preputial secretions and the ejaculate are unlikely vehicles for shedding of the virus.

Latency

Pigs that recover from infection are latent carriers of the virus for life. Reactivation, followed by shedding and spreading the virus, may occur following stress such as transport or farrowing, or by the administration of corticosteroids.\textsuperscript{41,42} Serological testing of latent carriers detects the antibody response to the whole virus or to a pseudorabies virus glycoprotein.\textsuperscript{43} During natural infection, the virus replicates at the site of infection, usually in the oronasal areas. The virus gains entry into the nerve endings and ascends by retrograde axonal transport, to the cell body in the trigeminal ganglion. Viral components can be found in both the trigeminal ganglion and the tonsils.\textsuperscript{44,45} The tonsil is a primary site of virus replication and serves as an area for monitoring virus shedding during acute infection and reactivation. The virus can be isolated from tissue fragments of pigs clinically recovered from disease for up to 13 months and followed by a challenge with the live virus, which may be shed by sows for up to 19 months after initial infection. Virus gene products can be found in the trigeminal ganglia and tonsils for many weeks following acute infection.\textsuperscript{44} Latent infection can also occur in vaccinated pigs.

Other species

The rarity of spread to other species is due to the scanty nasal discharge and the impracticality of the discharge coming into contact with abraded skin or nasal mucosa of animals other than pigs. The disease has occurred in sheep and cattle following the use of a multiple-dose syringe previously used in infected swine. The disease may spread from normal or clinically affected pigs to animals of other species, but does not usually spread between animals of the other species. For example, sheep and calves can be infected experimentally, but there is no evidence that they excrete the virus. The disease may occur in pigs, sheep, and cattle on the same farm. Brown rats may be a minor source of infection but are unlikely to be an important reservoir; they are capable of spreading the disease to dogs. The wild Norway rat is thought to have only a minor role in the transmission of the disease to farm animals. The virus causes fatal disease in dogs, which are usually infected from close association with infected pigs. The raccoon can be infected experimentally, but is not considered to be a long-term subclinical carrier of the virus. The possible role of wild animals in transmission of pseudorabies in swine has been examined with inconclusive results. It has been seen in Kodiak, Polar and Himalayan bears fed on a diet of raw pig's heads.\textsuperscript{45} Five viral isolates were recovered from latently infected wild boar originating from two regions of East Germany,\textsuperscript{46} but in the Netherlands the wild boar were said to be rarely affected.\textsuperscript{47} The PRV infections in the wild boar in Germany are said to exist in the country as an endemic infection and persist completely separately to the domestic population and also do not appear to affect it.\textsuperscript{48} The sacral ganglia and trigeminal ganglia of wild pigs were said to be a source of infection.\textsuperscript{49} The latency was shown in 9/16 sacral ganglia, 7/16 trigeminal ganglia and 5/13 tonsils\textsuperscript{49} from feral swine in the USA, but even so most of the transmission in feral swine is expected to be venereal. There seems to be little evidence of a high infection rate in the wild boar of the Netherlands but they are in contact with the wild boar of Germany.\textsuperscript{50} It seems quite common in Spanish wild boar with 36% of a study of 78 being serologically positive. The wild...
boar strain is adapted to the wild boar pig. A group 1 virus was isolated from a wild boar in 1993 and it was suggested that the virus persisted for several years in the wild boar population in Italy. In Croatia, approximately 55% of tested wild boars were found to be seropositive. The experimental infection of wild boars and domestic pigs with different strains has been carried out and the clinical signs depended on the strain but the wild boar could infect the domestic strains and vice versa. The low virulence strains were highly adapted to the wild boar.

Immune mechanisms

When infected with a virulent strain of the virus, pigs develop an immune response that can completely, or almost completely, prevent the virus from replicating after the pig becomes reinfected. Following natural infection, sows acquire immunity, which is transferred to their piglets in the colostrum and persists in the piglets until 5-7 weeks of age. Following intranasal challenge, piglets with colostrum immunity from naturally infected sows are protected from clinical disease, but not against subclinical infection.

Vaccination of pigs with attenuated pseudorabies virus prevents clinical disease and death that may otherwise follow exposure to the virulent virus. Vaccination does not, however, prevent either acute or latent infection with virulent virus. As a consequence, vaccinated pigs, as well as non-vaccinated pigs that survive infection with the virulent virus, can become virus carriers and a source of the virus following reactivation of a latent infection. This is of vital importance in eradication programs wherein it is necessary to identify infected pigs regardless of their vaccination status. Maternal immunity interferes with inactivated virus vaccination much more than with live virus vaccination.

Vaccination of pregnant sows induces a maternal immunity, which protects piglets from experimental disease. However, latent infection of young pigs with highly virulent virus can develop in the absence of clinical signs. The virus can reach the uterine and fetal tissues, via infected mononuclear cells, the presence of circulating antibodies induced on vaccination. Vaccination of piglets before challenge exposure has little or no effect on the rate of establishment of virus latency, but vaccination does reduce shedding after subsequent experimental reactivation of the virus with dexamethasone. Attenuated thymidine kinase-negative vaccine strains of the virus can also establish a reactivatable, latent infection.

In growing and finishing pigs in quarantined herds, the serological status is unpredictable because the infection may continue to spread, may cease temporarily, or may cease altogether. Evaluation of the serological status of the boars in a breeding herd does not accurately reflect the serostatus of the herd.

It has been suggested that the T cells are more important than the B cells in the clearance of PRV from the host and it has been shown that strong T-cell mediated responses after challenge produce the best protection.

Economic importance

The economic losses associated with pseudorabies in swine are due to clinical disease, and the costs of serological analysis and vaccination programs. Because of the variability of expression of the infection in different herds, a description of a single farm's experience with pseudorabies is difficult to put into a larger perspective regarding the impact of disease at a state or national level.

Economic loss estimates must include the measurement of losses during and immediately after clinical outbreaks of disease, and the indirect losses incurred until after eradication of the disease. Losses have been estimated at US$25-50 per sow per year; these include only losses during the period of the outbreak and the direct losses attributable to death and abortions. When expanding the observations of economic losses to 3 months after the termination of the outbreak, estimated losses may be as high as US$145 per sow per year.

Economic analyses of the losses in a commercial farrow-finish herd of 240 breeding age sows in the United States revealed that the major part of the loss was caused by death of suckling pigs at 70% of total loss, nursery pig mortality accounted for 12.6% of total net loss, sow culling and deaths accounted for 9.4% of net loss, and market pig deaths accounted for 1.2% of net losses.

The costs of eradicating pseudorabies vary depending on the methods employed. Depopulation-repopulation is the most expensive method because it requires culling of animals, clean-up costs, and downtime which represents the largest proportion of expense. In addition, the probability of reinfection following repopulation is a risk.

Test and removal is the most inexpensive, and segregation of offspring is intermediate in costs. The cost of eradicating the virus from a swine herd can be in excess of US$220/inventoried sow; some estimates are much higher. In large breeding herds or finishing herds with the continual influx of susceptible pigs, the disease may become endemic. Pseudorabies may also be a significant cause of reproductive inefficiency in pigs, and infection within the herd may be initially manifest by abortions in the sow herd, followed later by the more typical occurrence of neurological disease in suckling and growing pigs. The economic losses due to the disease can be very high because of mortality in young pigs, decreased reproductive performance, and the necessity to depopulate to eradicate the disease from a herd. An economic assessment of an epidemic of pseudorabies in a 150-sow farrow-finish operation on selected production and economic variables has been made. The mean litter size remained the same throughout the period of observation, but there was a two-fold increase in suckling pig mortality and 3.5-fold increase in stillbirths during the months of the epidemic compared with the period before the epidemic. Following the epidemic, suckling pig mortality was 14% greater and stillbirth rate was 71% greater than during the months preceding the outbreak. The major economic losses (88% of the total loss) were related to breeding herd removal/depopulation and production downtime.

PATHOGENESIS

The portal of entry is through abraded skin or via the intact nasal mucosa. The virus is pantropic and affects tissues derived from all embryonic layers. Receptor and receptor-binding virion proteins which can mediate the virus entry into the cell and cell to cell spread have been described. The various glycoproteins of the virus are required for various stages of virion morphogenesis. For example deletion of glycoproteins gE, gI, and gM inhibits the virion maturation. Pseudorabies glycoprotein gK is a virion structural component involved in virus release from the cell but not viral entry and its presence is important to prevent immediate reinfection. Viremia occurs with localization of the virus in many viscera, but with multiplication occurring primarily in the upper respiratory tract. Spread to the brain occurs by way of the olfactory, glossopharyngeal, or trigeminal nerves i.e. via the autonomic nerves. Cells with the common leukocyte antigen CD45+ populate the CNS infected areas from the local capillaries and the number of cells is increased in proportion to the number of infected neurons. Virus disappears from the brain by the 8th day, coinciding with the appearance of neutralizing antibody in the blood. When
the virus gains entry through a skin abrasion, it quickly invades the local peripheral nerves, passing along them centripetally and causing damage to nerve cells. It is this form of progression that causes local pruritus in the early stages of the disease, and encephalomyelitis at a later stage when the virus has invaded the central nervous system. In pigs, pruritus does not develop after IM injection, but a local paralysis indicative of damage to low motor neurons occurs prior to invasion of the central nervous system in some pigs. In cattle, pruritus of the head and neck is usually associated with respiratory tract infection, while perianal pruritus is usually due to vaginal infection.

Inoculation of the virus into the nasal cavities or brain results in signs of encephalitis rather than local pruritus. With oral inoculation there is an initial stage of viral proliferation in the tonsillar mucosa, followed by systemic invasion, localization, and invasion of the central nervous system along peripheral and autonomic nerve trunks and fibers. Lesions of Auerbach’s myenteric plexus and the skin may also occur. The peripheral blood mononuclear cells, tonsil, lymph nodes and bone marrow are poor source of virus after experimental infection.

The virus may be present in the trigeminal ganglion of a naturally infected sow without any history of clinical disease. Experimental inoculation of the virus into young pigs can result in a mild pneumonia which may progress to a severe suppurative bronchopneumonia. The virus can invade the uterus and infect pre-implantation embryos, which can lead to degeneration of the embryo and reproductive failure. Virulent pseudorabies virus can cause lesions in the uterine endometrium and ovarian corpora lutea of pigs in early pregnancy, and gene-deleted mutant virus vaccine given IV during estrus can cause ovarian lesions, which may affect fertility.

Through the use of embryo transfer procedures, infected embryos may disseminate the virus from donors to recipients.

**CLINICAL FINDINGS**

The incubation period in natural outbreaks is about one day.

**Pigs**

The major signs are referable to infection of the respiratory, nervous and reproductive systems. There is considerable variation in the clinical manifestation, depending on the virulence and tropism of the infecting strain. Nervous system disease is the major manifestation, but with some strains, respiratory disease may be the initial and prime presenting feature. There is also strain variation in the pattern of age susceptibility.

Young pigs a few days to a month old are most susceptible. Very young sucklings develop an indistinct syndrome, but prominent nervous signs occur in older piglets. A febrile reaction, with temperatures up to 41.5°C (107°F), occurs prior to the onset of nervous signs. Incoordination of the hindlimbs causing sideways progression is followed by recumbency, fine and coarse muscle tremors, and paddling movements. Lateral deviation of the head, frothing at the mouth, nystagmus, slight ocular discharge, and convulsive episodes appear in a few animals. A snoring respiration with marked abdominal movement occurs in many, and vomiting and diarrhea in some affected pigs. Deaths occur about 12 hours after the first signs appear. In California, a consistent sign has been blindness due to extensive retinal degeneration.

In growing and adult pigs, the disease is much less severe but there is considerable variation depending upon the virulence of the infecting strain. In growing pigs, mortality falls with increasing age and is generally less than 5% in pigs at 4–6 months of age. With some strains, fever is a prominent sign, while depression, vomiting, and sometimes marked respiratory signs, including sneezing, nasal discharge, coughing, and severe dyspnea are common. Trembling, incoordination, and paralysis and convulsions follow, and precede death. With others, the disease may manifest at this age by mild signs of posterior incoordination and leg weakness. Concurrent infection has been described with both PCV2 and ADV.

In adults, fever may not be present and the infection may cause only a mild syndrome of anorexia, dullness, agalactia, and constipation. However, virulent strains may produce acute disease in adults, characterized by fever, sneezing, nasal pruritus, vomition, incoordination and convulsions, and death. Infection in early pregnancy may result in embryonic death, or abortion, and early return to heat. An abundant vaginal discharge may occur. Infection in late pregnancy may result in abortion, or in the subsequent birth of mummified fetuses, which may involve all or only part of the litter. Abortion may result from the effects of fever or from viral infection of the fetus.

**Cattle, sheep, and goats**

There may be sudden death without obvious signs of illness. More commonly, there is intense, local pruritus with violent licking, chewing, and rubbing of the part. Itching may be localized to any part of the body surface, but is most common about the head, the flanks, or the feet, the sites most likely to be contaminated by virus. There is intense excitement during this stage, and convulsions and constant bellowing may occur. Maniacal behavior, circling, spasm of the diaphragm, and opisthotonos are often evident. A stage of paralysis follows in which salivation, respiratory distress, and ataxia occur. The temperature is usually increased, sometimes to as high as 41–41°C (106–107°F). Final paralysis is followed by death in 6–8 hours after the first appearance of illness. A case of non-fatal pseudorabies in a cow is recorded. There is also a report of pseudorabies occurring in feedlot cattle in which there were nervous signs, bloat, and acute death, but no pruritus. In young calves, it is characterized clinically by encephalitis, no pruritus, erosion in the oral cavity and esophagus, and a high case fatality rate. An outbreak in sheep was associated with skin abrasions acquired at shearing. Affected ewes were dull, inappetent, and had a fever of 41.1°C. About 23 of 29 affected sheep developed the ‘mad itch’, with nibbling of their fleece and frenzied attempts to bite one area of the skin and rub it against the wall and bars of their pen. Terminally, recumbency, tremors, and opisthotonos were common, and death occurred within 12–24 hours after onset.

In France, cases in dogs have been linked to strains of virus from wild boars.

**CLINICAL PATHOLOGY**

**Serology**

The commonly used serological tests for pseudorabies-specific antibodies are the serum-neutralization (SN) and ELISA.

**Serum neutralization test**

The SN test using the Shope strain has been the ‘gold standard’ against which other serological tests are compared and has been most widely used because of its sensitivity and specificity. Specific virus-neutralizing antibodies are detectable in the serum of recovered pigs, and this test is in routine use for herd diagnosis and survey purposes. Antibody is detectable on the 7th day after infection, reaches a peak about the 35th day, and persists for many months. Paired serum samples taken as early as possible, and about 3 weeks later, show a marked antibody
rise. However, the SN test lacks the sensitivity necessary for detection of pigs with low levels of humoral titer of specific SN antibodies which can be enhanced by using the Bartha gII strain.72

Some herds may have no serological evidence of previous infection or current spread of the virus, but have single reactors in the herd which may be infected with the virus.73 Such singleton reactors may be found in herds being monitored serologically for presence of infection. These singleton reactors may be infected with strains of the virus that are relatively avirulent.

Enzyme-linked immunosorbent assay

The ELISA is more sensitive than the SN test, especially early in the immune response to pseudorabies antigens. However, because of its high sensitivity, screening ELISAs yield some false-positives which must be confirmed by another test, such as another ELISA, SN test or latex agglutination test.74 False-positives are unlikely to be due to infection with other herpesviruses. ELISA has also been used as a meat juice test75 with high sensitivity (93%) and specificity (98%). The indirect ELISA is a more rapid and convenient procedure, offering many advantages over the SN test for routine serodiagnostic work. An indirect ELISA, using whole blood collected onto paper discs, is a rapid and convenient test and eliminates the costs of using vacutainer tubes and separating the blood. An indirect ELISA based on recombinant and affinity-purified glycoprotein E of PRV to differentiate vaccinated from naturally infected animals has been developed.77 An indirect ELISA has been developed in the Czech Republic79 that can be used because of its high sensitivity and specificity for blood serum or frozen pork samples. It has allowed the demonstration of ADV in meat juice with only marginal titers in the blood. Commercial ELISA kits are available and some are more specific than others.74 A highly sensitive and specific competitive ELISA based on baculovirus expressed pseudorabies virus glycoprotein gE and gI complex has been described.79 This allows detection as early as 2 weeks post-infection and can handle large numbers of tests without the need to handle live virus.

In countries where vaccination is regularly used for control of the disease, an assay to serologically distinguish infected from vaccinated pigs is critical. While a vaccination program will reduce the circulation of virus in the field, it will not eliminate the virus from the pig population. To eradicate the virus, the ability to differentiate infected from vaccinated pigs is crucial. Several commercial ELISA kits can differentiate between vaccinated and naturally infected pigs.80 Differentiation is possible when vaccine virus strains have either a natural, or a genetically engineered, deletion that encodes for either glycoprotein-I (gI), gII, or gX genes. Commercial ELISA kits that specifically detect antibody responses to gI of the virus offer considerable advantages as diagnostic tests for the virus, with a sensitivity of 99.2% and specificity of 100%.80 The gI ELISA is able to distinguish infected pigs from those vaccinated with gI-negative vaccines.81,82 The field strains of the virus produce antibodies to gI when inoculated into pigs. Unvaccinated pigs, or pigs vaccinated with gI-negative vaccines, that become subclinically infected with field strains of the virus may be detected with the gI-ELISA for a long time after infection. Thus, pigs that are seropositive in the gI-ELISA have either been infected with the pseudorabies virus or have been vaccinated with gI-positive vaccines; gI-seronegative pigs can be considered to be uninfected. Eradication of the virus from swine herds is possible by gI-ELISA testing, and culling gI-seropositive pigs in herds using gI-negative vaccines.

Detection of pigs in the latent phase of infection can be done serologically.43 Pigs of any age that survive the acute infection phase become latent carriers for life, and serologic testing consistently detects animals in the latent phase of infection if the test detects the antibody response to the whole virus or to a reliable pseudorabies-virus glycoprotein.43 Of several serological tests examined, the glycoprotein-I and glycoprotein-III marker systems, which performed with similar sensitivity as the screening tests, were superior to the glycoprotein-X marker system in detecting antibodies in infected pigs.

Detection of virus

In infected pigs the virus is usually present in nasal secretions for up to 10 days. A common method for the diagnosis of pseudorabies in sows is to take swabs from the nasal mucosa and vagina. Polyester and wire swabs shipped in 199 tissue culture medium supplemented with 2% fetal bovine serum (FBS) buffered with 0.1% sodium bicarbonate and HEPES will yield optimum recovery of the virus. Wooden applicator sticks with cottonwool have antiviral activity and recovery of the virus may not be possible after 2 days, which is of practical importance if the samples are shipped by mail. The virus can be demonstrated in nasal cells by immunofluorescence and immunoperoxidase techniques.85 The virus can be detected by direct filter hybridization of nasal and tonsillar specimens from live pigs.44 The virus survives on tonsil swabs taken with Dacron-tipped applicators for up to 72 hours in cell culture medium under transport.84

New PCR techniques have been used and have been used to differentiate between true and false serological positives when single reactor pigs have been found.85

NECROPSY FINDINGS

There are no gross lesions typical and constant for the disease, and diagnosis must rely on laboratory examination. When pruritus has occurred there is considerable damage to local areas of skin, and extensive subcutaneous edema. The lungs show congestion, edema, and some hemorrhages. Hemorrhages may be present under the endocardium and excess fluid is often present in the pericardial sac. In pigs, there are additional lesions of visceral involvement. Slight splenomegaly, meningitis, and excess pericardial fluid are observed, and there may be small necrotic foci in the spleen and liver. Foci of hepatic necrosis may also be seen in aborted fetuses. Histologically, in all species, there is severe and extensive neuronal damage in the spinal cord, paravertebral ganglia, and brain. Perivascular cuffing and focal necrosis are present in the gray matter, particularly in the cerebellar cortex. Intraneural inclusion bodies occur infrequently in the degenerating neurons and astroglial cells, particularly in cerebral cortex in the pig. These inclusions are of considerable importance in differential diagnosis. Necrotizing lesions with inclusion-body formation in the upper respiratory tract and lungs is strongly suggestive of porcine pseudorabies. Ultrastructural observations have been made which included syncytia, cellular debris and macrophages and lymphocytes with vacuoles in their cytoplasm.86 Virus may be detected by direct fluorescent antibody examination or by growth in tissue culture. The tissues of the head and neck regions of non-immune pigs yield virus most consistently and in the highest concentration after challenge. The immunoperoxidase test can be used to study the distribution of the virus in different tissues. Latent virus can be detected using a DNA hybridization dot blot assay. Where possible, whole carcasses and fetuses should be submitted for laboratory examination. The location of the optimal neural samples, including the paravertebral ganglia, has been described for sheep.87 The placental lesions in pregnant sows that have aborted from...
natural infection with pseudorabies consist of necrotizing placentitis and the presence of intranuclear inclusions. In an experimental infection of loops of intestine it was shown that there was necrosis of the follicles in the Peyer’s patches and degeneration of the epithelial cells in the crypts and villi and degeneration of the cells in the myenteric plexuses. Intranuclear inclusion bodies were found 2–4 days after inoculation. The primary target of the wild ADV was the macrophages of the sub-epithelial area of the dome of the Peyer’s patch.

Samples for confirmation of diagnosis
- **Histology** - one half of midsagittally-sectioned brain, spinal cord with paravertebral ganglia, Gasserian ganglion, placenta, liver, lung, spleen, tonsil, retropharyngeal lymph node (LM). Immunohistochemistry has been used to confirm rare cases in countries where the disease is rare and other corroborating evidence is lacking. Can also collect muscle samples for meat juice ELISAs.
- **Virology** - brain, spinal cord, liver, spleen, tonsil, retropharyngeal lymph node (FAT, ISO). CSF is not good for virus isolation.

**Differential Diagnosis**
The different clinical forms of pseudorabies in pigs and ruminants resemble several diseases.
- **Teschen disease** occurs in similar forms in certain areas; the diagnosis is dependent on serology and pathology.
- **Rabies** is rare in pigs and is usually accompanied by pruritus at the site of the bite.
- **Streptococcal meningitis** is restricted to suckling pigs of 2–6 weeks of age, the lesions are usually obvious at necropsy, and the causative organism is readily cultured from the meninges. The response to treatment with penicillin is good and is of value as a diagnostic test.
- **Encephalopathy** associated with hog cholera, African swine fever, salmonellosis, Gasser’s disease, *Escherichia coli* septicemia and erysipelas are considerations, and are usually obvious at necropsy.
- **Bowel edema** causes typical edema of the head and eyelids, undu typical circumstances in younger pigs and rapid death.
- **Salt poisoning** causes typical intermittent nervous signs, with a typical history of water deprivation.
- **Respiratory form of pseudorabies** should be considered in any outbreak of respiratory disease that is poorly responsive to usually effective therapeutic measures.

**Reproductive inefficiency associated with enterovirus (SMEDI) and parovirus infections** closely resembles that associated with pseudorabies, and requires laboratory differentiation by virus isolation and serological testing. In cattle the local pruritus is distinctive, but the disease may be confused with the nervous form of acetonemia in which paresthesia may lead to excitement. The rapid recovery that ordinarily occurs in this form of acetonemia is an important diagnostic point. The furious form of rabies and acute lead poisoning cause signs of mania, but pruritus does not occur.

**TREATMENT**
There is no treatment.

**CONTROL**
The control of pseudorabies is difficult and currently unreliable because normal healthy pigs may be infected and shed the virus for up to several months.

An important principle in control and eradication of the disease is the reproduction ratio, $R_0$, which is defined as the average number of new infections caused by one typical infectious animal. When $R_0 > 1$, the infection can spread; when $R_0 < 1$, the infection will disappear. In eradication programs it is essential that $R$ be less than 1 and the infection will die out in the herd.

**Strategies available**
The methods of control or eradication include depopulation and repopulation, test and removal, segregation of progeny, and vaccination. The selection of a strategy for the control or elimination of the disease depends on the following:
1. Source of the herd infection
2. Method of transmission of the virus
3. Survival of the virus in the environment
4. Sensitivity and specificity of the diagnostic test
5. Risk factors in the herd, which include:
   - type of operation
   - degree of herd isolation
   - prevalence of infection
   - value of the genetic material
   - level of management expertise
   - availability of suitable virus-free replacement swine
   - depopulation and repopulation is chosen as a strategy.

The eradication of the disease from small herds was described in Hungary. In this country the shared use of boars, the pig density and the infection in the surrounding area were the most significant influences on the spread and control of the disease.

Breeding stock producers favor eradication, farrow–finish producers that do not sell breeding stock or feeder pigs are generally more concerned with the reduction of losses from clinical pseudorabies infection than with eradication. In the USA offsite all in/all out finishing was more frequent amongst the successful farms than the unsuccessful. The unsuccessful also had other infected herds within 3.2 km (2 miles) and often no cleaning or disinfection.

**Economics of control and eradication**
Depopulation–repopulation is the most expensive, segregation of progeny method is next, and the test and removal the most inexpensive per sow. A computerized decision-tree analysis and simulation modeling can evaluate the economics of control and eradication strategies. The optimal alternative is to test and remove seropositive animals if the initial prevalence is ~57%; otherwise vaccination of sows only is preferred. Vaccination may be recommended at lower prevalence rates as a conservative approach. Eradication by test and removal combined with the use of gene-deleted vaccines is advantageous at any prevalence rate of infection.

In Sweden, it was estimated that an eradication program is economically viable. The maximum benefits are derived where the Swedish agricultural sector is deregulated and consumers obtain about 50% of the benefits excluding program costs. In the current case where Sweden is a member of the European Union, the benefits are reduced mainly due to lower prices of inputs and pork.

An economic analysis of alternative control programs found that, for regions of high pig density, the most economical strategy is to lower herd prevalence by...
Intensive vaccination before completing eradication by test-and-removal of remaining positive animals. The eradication and control programs used in France have been reviewed. The eradication of PRV in a 170 sow herd was described in which the affected animals were killed and the rest were then vaccinated and the total cost to the farm was about $50 000.

Determination of prevalence of infection
In large herds, the virus must be eliminated from the growing-finishing pigs and the breeding herd. Large herds that are virus-positive are infected in both groups; smaller herds are frequently infected in only the breeding herd. An initial step in eradication is to determine the prevalence of infection. Representative samples of finishing pigs older than 4 months, and of breeding sows, gilts, and boars are tested. On the basis of the test results and the risk factors in the herd, a cost-effective plan can be devised for the individual herd.

Depopulation and repopulation
When the prevalence of infection in the herd is over 50%, eradication can be achieved by depopulation and repopulation with virus-free breeding stock. However, depopulation is the most expensive method and is not compatible with the retention of valuable pedigree stock. The entire herd is depopulated over a period of months as the animals reach market weight. After removal of the animals the entire premises are cleaned and disinfected. Repopulation should be delayed at least 30 days after the final disinfection, and swine should originate from a pseudorabies-negative herd and be isolated on the premises and retested 30 days after introduction. All herd additions should be isolated and tested 3 days after introduction.

Test and removal
The test and removal program is recommended when the prevalence of infection in the herd is below 50%. This method requires testing of the entire breeding herd and immediate removal of all seropositive animals; 30 days after removal of seropositive animals, the herd is retested, and if necessary at 30-day intervals, until the entire herd tests are negative. Following a second negative test, the testing regimen may be changed to test only 25% of the herd every 4 months. Seropositive animals are identified and culled. The test and removal method is superior to the vaccination system as a method of control. Valuable genetic material from breeding stock that are seropositive may be salvaged using embryo transfer techniques. Embryos may be transferred safely to susceptible recipient gilts from sows that have recovered from infection, but not from sows that are in the active stages of infection. The virus does not penetrate the outer covering of the embryo, but it can become attached to it so that it may physically transfer to the uterus of the recipient. This transfer of infection may occur if the donor sow is in the active phase of infection.

Offspring segregation
The objective of this strategy is to raise a pseudorabies-negative breeding herd to replace the infected herd. Once the herd is diagnosed as pseudorabies-infected, a regular schedule of vaccination is instituted. Gilts are vaccinated at first breeding, and both sows and gilts are vaccinated 2-4 weeks before farrowing to provide a high level of colostral immunity to their piglets. Offspring are removed at weaning and raised apart from the infected herd. At 4 months of age, and again before breeding, the segregated replacements are tested for antibody. Since colostral immunity is no longer detectable by 4 months of age, any animals over 4 months of age that are seropositive are considered pseudorabies infected. As the gilts reach reproductive maturity, the old sow herd is replaced. Segregation between the infected sow herd and the clean gilt herd is maintained until all positive sows have been removed and the facilities disinfected. Groups of seronegative pigs are identified and combined into large groups to establish a new herd. The original herd is gradually depopulated, and the premises cleaned and disinfected. The new herd is then monitored on a regular basis.

Control programs in effect
Pseudorabies was first diagnosed in the North Island of New Zealand in 1976, an eradication program started in 1989 and the virus was cleared from the North island in 1997.

A pseudorabies control program was introduced in England in 1983 when the infection was spreading rapidly. New legislation imposed restrictions on the movement of pigs where clinical signs of the disease were present in the herd. The first part of the eradication scheme involved testing all of those herds previously known to have pseudorabies. Within several months after the beginning of the eradication campaign, 417 herds had been slaughtered, involving 342 275 pigs, of which 72.5% were salvaged. Only 121 herds had been known to be previously infected, while the remaining 296 herds had been identified through traceback and reports of new cases. By 1985 it was concluded that the disease was well-controlled in England with only 10-14 infected herds remaining. Farmers were compensated for all animals slaughtered and also for consequential loss associated with the loss of stock. The cost of the eradication program was financed by a levy on all pigs normally marketed for slaughter in England. In 1995, England was free of Aujeszký's disease. Following the successful use of the gene deletion vaccination and eradication program the Netherlands is now free and also Germany. There were originally 70% seropositive sows in 1993, 1% in 1998 and now none (as above). In Sweden the herds were declared free from 12-53 months after the start of the programme. Now in Northern Ireland, pseudorabies is more widespread than it ever was in Britain before the eradication program. Because the infection rate is over 50%, an eradication program based on slaughter of infected herds would destroy the swine industry. Thus the control program in Northern Ireland is based on the use of vaccination, the culling of seropositive animals, and the gradual introduction of seronegative animals.

In the United States, the national pseudorabies eradication program was implemented in 1989 as a joint State-Federal-Industry-sponsored program. Pilot projects were conducted in Iowa, Illinois, Pennsylvania, Wisconsin, and North Carolina from 1984 to 1987. In the pilot projects, 97.5% of 116 herds that were initially pseudorabies-positive were successfully cleared of infection. This indicated that eradication of pseudorabies virus from herds of swine can be efficiently achieved, and is most effective on a regional basis. The eradication of the gene-deleted pseudorabies vaccines in the program was the technical breakthrough needed to be able to offer the national eradication program, since it was now possible to distinguish between naturally infected and vaccinated animals. The program consisted of:

Stage 1, preparation
Stage II, control
Stage III, mandatory herd clean-up
Stage IV, surveillance
Stage V, free.

In Ohio, the eradication has made progress and eradication is expected in 1996 at a minimum cost to the public and the process in Illinois has also been described. In practice what it meant was that all were at stage I by 1991, stage II was in states with over 1% affected and stage III in the states with less than 1% affected, there were still 10 states in stage IV on 1/1/2000 but on the 1/1/2000 33
states were free and all were cleared by 2002. When an outbreak of the disease occurs in a susceptible herd the mortality may be very high, and the first consideration is to prevent spread to uninfected sows and litters and pregnant sows from infected pigs. They should be attended by separate personnel, or adequate barriers to mechanical transmission of infection should be arranged. On affected premises, cattle should be kept from the area. The affected herd should be quarantined, and all pigs sold off the farm should be for slaughter only.

Vaccines and vaccination

Vaccination is used to reduce clinical disease when outbreaks occur or when the disease is endemic in the herd. An effective immunity develops after natural infection or vaccination, and piglets from immune sows are protected from clinical disease during the nursing period by colostral immunity. However, the presence of circulating antibody does not prevent infection, the development of latency and subsequent activation and excretion of the virus. However, vaccination reduces viral shedding after natural infection. On farms in which the disease is endemic or outbreaks have occurred, vaccination of the sows, and management procedures to reduce the spread of infection, have markedly reduced preweaning mortality and reproductive failures. Field studies in large numbers of herds where the sows were vaccinated three times annually show that the reproduction ratio was below 0.66, which is significantly below 1, and massive spread of the virus does not occur.

It is often virtually impossible to prevent the spread of infection in a susceptible herd and vaccination of all pigs at risk, especially pregnant sows, is recommended. The vaccine reduces losses in infected herds, limits the spread of infection, and decreases the incidence in endemic areas. With a properly controlled and monitored vaccination and culling program in a breeding herd it is possible to control clinical disease and reduce the infection pressure. All breeding stock present during an outbreak are subsequently vaccinated regularly until they are all culled, which removes the major sources of virulent virus. Following this phase, newly introduced gilts and boars are tested, and monitored regularly. This is considered to be less costly than the test and slaughter policy.

However, in vaccinated herds, the virus continues to circulate and an accurate epidemiological analysis is not possible because titers caused by vaccination cannot be distinguished from those caused by natural infections. Control of the diseases in many countries has always been based on compulsory intensive vaccination of the entire population.

Vaccines

Conventional modified live virus and inactivated virus vaccines have been available. Both vaccines will reduce the incidence rate and severity of clinical disease in an infected herd. They also reduce the field virus shedding and latency in the trigeminal ganglion after exposure to field virus. The vaccine efficiency is however markedly influenced by the modified live virus vaccine strain and the route of administration. The vaccine genotype plays a very important role in the effectiveness of the vaccine program. Recently needle-free transdermal vaccination using a modified live PRV vaccine has been described thereby preventing the loss of any needles in the carcass. Cell mediated immunity in the form of cytotoxic T-cells may play an important part in the effectiveness of the vaccine. The deficiencies of inactivated vaccines in producing virus specific interferon gamma (IFN) can be enhanced by the use of simultaneous administration of IL-12 which appears to upregulate Th1/Th2 expression.

Pregnant sows

Vaccination of pregnant sows induces SN antibodies, which are transferred to the newborn piglets and provide protection against infection. Vaccination during pregnancy produces more protection against PRV for piglets than sow vaccination before mating. A better protection was observed in sows vaccinated with an attenuated virus than in sows vaccinated with inactivated virus. Piglets rely on colostral and milk antibodies for protection, and the vaccination of piglets born from vaccinated sows does not produce a significant serological response until the piglets are about 12 weeks of age. Earlier vaccination of piglets from infected or vaccinated sows is ineffective because high levels of maternal antibodies interfere with a serological response stimulated by the vaccine.

Maternal immunity interferes with the development of active immunity from vaccination until at least 15 weeks of age, even when the colostral titers are low. Thus, in a situation in which the majority of sows have been infected or vaccinated, vaccination of weaned pigs may not yield desirable results. Both inactivated virus and attenuated live virus vaccines provide similar results when piglets born from vaccinated sows are vaccinated before colostral immunity has waned.

Growing and finishing pigs

The optimal vaccination strategy for growing and finishing pigs in an eradication program is controversial. In eight persistently infected herds vaccinations, both I/N and I/M were made at 4 and 10 weeks of age. Only one vaccination is given to finishing pigs in endemic areas in Europe. However, this does not reduce the prevalence of infection in finishing pigs in herds with a high prevalence. Double vaccination of finishing pigs will reduce the spread of the virus, but extensive spread can still occur. The presence of maternal antibodies may interfere with the induction of antibodies, and double vaccination 4 weeks later may boost immunity. Mean daily weight gain was also improved by a second vaccination with a direct economic benefit.

Marker or subunit vaccines

A major development in vaccination against pseudorabies has been the introduction of genetically engineered live vaccine strains used to make marker or subunit vaccines. Vaccination with modified live gene-deleted vaccines is now an integral part of pseudorabies eradication programs worldwide. The most common gene deletions are for glycoproteins E (gE) or gI and G (gG) or gX, and gIII. A gD/gE negative vaccine was described. In Europe, use of gE-marked vaccines has become the standard. In the United States, a gG–gE– pseudorabies vaccine has been introduced. These vaccines in conjunction with a companion diagnostic test, can distinguish between naturally infected and vaccinated animals. Colostrum can also be used to monitor antibodies against gI protein of the virus.

A study comparing I/N and I/M vaccination showed that pigs given both vaccines (I/N and I/M) had a significantly better clinical and virological protection after challenge than the single I/N vaccination. The recombinant vaccines are able to circumvent the inhibition of active immunity that occurs when maternally derived antibody is still present. Animals vaccinated with a deleted vaccine are not able to mount an immune response against the protein whose gene has been deleted in the vaccine virus genome. In contrast, wild-type virus–infected animals produce antibodies against all the viral glycoproteins. Differentiating ELISAs, specific for the deleted marker protein, then allow discrimination between infected animals, which can be culled from the herd, and vaccinated animals. These vaccines reduce the severity of clinical disease and viral shedding. However, the presence of colostral antibodies in growing pigs may
which may result in increased virus excretion on challenge exposure. Repeated vaccination is needed to provide some protective immunity against challenge exposure to virulent virus.

These mutants have also been rendered thymidine kinase-deficient (TK-) mutants, and are avirulent and immunogenic. Pigs inoculated with these mutants are resistant to experimental challenge with the virulent virus, and the virulent virus cannot be recovered from the ganglia, which suggests that vaccination reduced colonization of the ganglia. The ideal vaccine strain should prevent clinical disease and mortality, should not be transmitted to non-immunized animals, should prevent colonization of the ganglia by a potential superinfecting virulent virus and thereby reduce the natural reservoir of the virus. The TK-mutant virus possesses these desirable characteristics. The high efficacy of recently constructed gI-negative deletion mutant vaccines of pseudorabies virus provide a sound basis for implementing the gI' approach to the future control of the disease.

Piglets born from sows vaccinated with deleted (gIII-, TK) strains at 3 days and 9 and 11 weeks of age developed detectable antibodies that lasted up to 100 days of age when vaccinated. Maternal antibodies in piglets from sows vaccinated with gIII-deleted vaccine decay to undetectable levels at 7 weeks of age. Vaccination of these piglets at 3 days of age with the same vaccine results in a priming effect, which protects the piglets against virulent virus challenge at 7 weeks of age. Thus, effective protection could be provided by active immunization from birth through weaning, in the nursery and into the growing and finishing stages of production.

Although genetically engineered live virus vaccines have been shown to be efficacious and safe, there is a possibility of spread between vaccinated and unvaccinated animals, of persistence in the field and of recombination between different vaccine strains, which can lead to enhanced virulence. New viral mutants lacking glycoproteins gD, gE, gG, and gI may form the basis for the development of new vaccines that do not recombine. A gB deletion vaccine has been described for I/N use and has been shown to produce both local and serum antibodies. Recently, a DNA vaccine was shown to give as good a response as gD plasmid vaccine but the DNA vaccine had to be given intradermally. It can overcome maternally derived antibody and the vaccine described in this case still gave protection against infectious PRV challenge at the end of the finishing period.

Even more radical is a vaccine with a granulocyte-macrophage colony stimulating factor (GM-CSF) which has also been given in a DNWA formulation. Experimentally, immunized pigs can be latently infected with the wild-type virus without being detected by the gE-specific ELISA routinely used to discriminate between infected and vaccinated pigs. Thus, gE seronegative pigs may still be infected and be a source of infection.

Remarkable progress has been made with the use of gI-deleted vaccines. Intensive regional vaccination of finishing pigs with a gI-deleted vaccine along with companion diagnostic tests, reduced the seroprevalence in infected herds from 81% to 19% in 2 years. Vaccination increases the virus dose needed for establishment of infection, and decreases the level and duration of virus excretion after infection. In the control group, with routine disease control, no significant change in seroprevalence occurred. The consistent application of intensive vaccination of all breeding herds in a region, including those herds participating in a production chain, can also decrease the prevalence of infection in heavily infected areas. The intensive regional vaccination did not completely eliminate virus infections within these herds; the source of infection was not determined. It is suggested that the virus either circulated at a low level within herds, or its introduction or reactivation did not lead to an extensive spread of the virus. A voluntary vaccination program on individual farms was unsuccessful in reducing the prevalence of virus-infected breeding pigs. The importation of breeding stock from outside the area is associated with a higher prevalence of virus-infected pigs because of lack of vaccination. The introduction of infections can be reduced by purchasing virus-free animals and by increasing farm biosecurity procedures.

Vaccination of breeding herds three times annually to insure a high level of immunization can lead to elimination of the disease when the reproduction ratio is less than 1. The method used for vaccination may influence the effect of the vaccine. Using glycoprotein vaccines, IM vaccination in the neck, and six-point 1D vaccination in the back provided the best protection; six-point 1D injections resulted in a better vaccination than two-point injections. Body weight changes and viral excretion after challenge were compared with virus-neutralizing titers, antigen-specific IgG and IgA responses in serum, and virus-specific lymphoproliferative responses in peripheral blood during the immunization period.

An intensive eradication program in farrow–finish herds using a gI-deleted vaccine in breeding and growing–finishing pigs, and decreases of movement, and mixing of growing–finishing pigs was successful in 3 years. The initial goal was to decrease viral spread in the growing–finishing pigs, which enabled production of seronegative replacement gilts. Increases in the number of sows culled, combined with an increase in the number of seronegative replacement gilts, resulted in a decrease in seroprevalence of sows. Bimonthly serological monitoring indicated minimal spread of the virus in the growing–finishing pigs after 1 year. Beginning at 18 months after initiation of the program, test and removal of seropositive sows commenced in all herds. All herds were released from quarantine within 3 years, indicating that eradication can be achieved by vaccination and management changes designed to minimize the spread of virus combined with test-and-removal procedures.

An attenuated gI-deleted–TK-deleted vaccine was used to eradicate the virus from a large farrow–finish herd in Sweden. At the start of the program, 86% of the breeding animals were seropositive. The breeding stock was vaccinated every 4 months and monitored serologically. Seropositive sows and boars were culled at an economic rate. The herd was declared gI-negative 39 months after the start of the program. Monitoring the herd for another 4 years, until all vaccinated animals had been culled, revealed the herd free of the virus.

In New Zealand, progress towards eradication using a subunit vaccine is reported. Those farms that combined vaccination with good management techniques, intensive testing and culling eradicated the wild virus infection within 2 years; those that made little or no progress has less than satisfactory standards of hygiene and did not practise an intensive testing and culling program. Vaccination of both breeding stock and growing pigs is recommended. A combined vaccination–eradication program for the disease would generally comprise four phases:

1. A systematic and intensive vaccination campaign
2. Screening of pigs for gI-antibodies
3. Economic culling of infected breeding pigs
4. Final ending of vaccination.

Piglets at 3 days of age can be vaccinated with one of these genetically engineered vaccines and be protected
from experimental challenge at 5 weeks of age. A recent study has shown that infection with PRRSv does not develop the infection-induced vaccine protection against PRV.  

**Vaccination of cattle** with an inactivated vaccine is recommended where they are in close contact with swine and where a low level of exposure is likely.

**VIRAL ENCEPHALOMYELITIS OF PIGS (TESCHEN DISEASE, TALFAN DISEASE IN THE UK, BENIGN ENZOOTIC PARESIS IN DENMARK, POLIOMYELITIS SUUM, PORCINE ENTEROVIRAL ENCEPHALOMYELITIS)**

**Etiology** Porcine enteroviruses capable of causing encephalomyelitis. Teschen virus, Talfan virus, and others

**Epidemiology** Certain European countries, Scandinavia, and North America. Morbidity 50%, case fatality 70-90%. Teschen in Europe. Talfan in UK. Viral encephalomyelitis in North America. Transmitted by direct contact

**Signs** Acute. Teschen. Fever, stiffness, unable to stand, tremors, convulsions, and death in few days. Subacute. Talfan. Milder than acute form. Most common in pigs under 2 weeks of age. Morbidity and case fatality rate 100%. Outbreaks. Hyperesthesia, tremors, knuckling of fetlocks, dog-sitting, convulsions, blindness, and death in a few days. Milder in older growing pigs and adults

**Clinical pathology** Virus-neutralization test

**Lesions** Non-suppurative encephalomyelitis

**Diagnostic confirmation** Demonstrate lesion and identify virus

**Differential diagnosis list**

- **Pseudorabies**
- **Herpetic encephalomyelitis virus**

**Treatment** None

**Control** Outbreaks will cease and herd immunity develops
ETIOLOGY
A number of closely related, but antigenically different, enteroviruses, capable of growth in tissue culture, are causes of encephalomyelitis in pigs. Porcine enteroviruses comprising at least 13 serotypes are grouped into three groups. They can cause neurological disturbances, infertility and dermal lesions in pigs. Teschen virus, initially isolated in Czechoslovakia, is the most virulent and there have been a number of independent isolates, such as the Konratice and Reporyje strains. Talfan virus, isolated from England, and other unnamed isolates appear less virulent. Teschen and Talfan virus occur in subgroup 1, which is now called porcine enterovirus group 1 (PEV-1) but isolates from encephalomyelitis are also associated with other subgroups. In 2001 it was proposed that the teschoviruses be regrouped into three with group 1 being the teschoviruses, group 2 the old PEV (V13 virus) and group 3 the old PEV9. In the system proposed these are PEV-A and PEV-B. It is now proposed that the PEV-1 Talfan group be regarded as a new genus for the family Picornaviridae. A recent study of group 2 suggests that it may have unique features and may be better called a new picornavirus genus. Within subgroups, strains may be further differentiated using a complement fixation test and monospecific sera. There is variation in virulence between strains, and with many strains, clinical encephalitis following infection appears to be the exception rather than the rule.

EPIDEMIOLOGY
Occurrence and prevalence of infection
Prior to the early 1940s, the incidence of porcine viral encephalomyelitis was restricted to certain districts in Czechoslovakia. Since then, reports of the disease have come from many countries and there is serological evidence that the disease occurs throughout the world. The most severe form of the disease - Teschen disease - appears to be limited to Europe and Madagascar, but the milder forms - Talfan disease, poliomylolystis suum, and viral encephalomyelitis - occur extensively in Europe, Scandinavia, and North America and recently in Japan. A recent outbreak in Indiana has been described and it was ascribed to porcine enterovirus serogroup 5 or 6 with the only characteristic feature being the histological lesions of polioencephalomyelitis. Losses due to the disease result primarily from deaths. Serological surveys in areas where the disease occurs indicate that a high proportion of the pig population is infected without any clinical evidence of the disease. In the majority of field occurrences, porcine encephalomyelitis is a sporadic disease affecting one or a few litters, or a small number of weaned pigs.

Morbidity and case fatality
The morbidity rate is usually about 50% and the case fatality rate 70–90% in Teschen disease as it is described in eastern Europe. The disease in Denmark and the United Kingdom is much milder, and the morbidity rate about 6%.

Methods of transmission
Infection is transmitted by ingestion and the aerosol routes. The virus replicates primarily in the intestinal tract but also in the respiratory tract. When infection first gains access to a herd the spread is rapid and all ages of pigs may excrete virus in feces.

Risk factors
Animal risk factors
Depending upon the virulence of the infecting strain, clinical disease primarily affects young pigs but may occur in older pigs at the same stage. As infection becomes endemic and herd immunity develops, excretion of the virus is largely restricted to weaned and early grower pigs. Adults generally have high levels of serum antibody, and suckling piglets are generally protected from infection by colostral and milk antibody. Sporadic disease in suckling pigs may occur in these circumstances in the litters of non-immune or low antibody sows, and may also occur in weaned pigs as they become susceptible to infection. In the recent outbreak in the USA the major factor was the rapid decline of the maternal antibody in the piglets (<21 days). Seroconversion then coincided with the increased mortality in the herd.

Pathogen risk factors
The causative viruses will infect only pigs and are not related to any of the viruses that cause encephalomelities in other species. They are resistant to environmental conditions, including drying, and are present principally in the central nervous system and intestine of affected pigs.

PATHOGENESIS
The virus multiplies in the intestinal and respiratory tracts and may invade the CNS. Infection of the CNS may follow, depending upon the virulence of the strains and the age of the pig at the time of infection. There is some strain difference in the areas of the CNS primarily affected, which accounts for variations in the clinical syndrome, and it is possible for histopathological evidence of encephalitis to be present in pigs that have shown no clinical signs of the disease. This may also occur with adenovirus infection.

CLINICAL FINDINGS
Acute viral encephalomyelitis (Teschen disease)
An incubation period of 10–12 days is followed by several days of fever (40–41°C, 104–106°F). Signs of encephalitis follow, although these are more extensive and acute after intracerebral inoculation. They include stiffness of the extremities, and inability to stand, with falling to one side followed by tremor, nystagmus, and violent clonic convulsions. Anorexia is usually complete, and vomiting has been observed. There may be partial or complete loss of voice due to laryngeal paralysis. Facial paralysis may also occur. Stiffness and opisthotonos are often persistent between convulsions, which are easily stimulated by noise and often accompanied by loud squealing. The convulsive period lasts for 24–36 hours. A sharp temperature fall may be followed by coma and death on the 3rd–4th day, but in cases of longer duration the convulsive stage may be followed by flaccid paralysis affecting particularly the hind limbs. In milder cases, early stiffness and weakness are followed by flaccid paralysis without the irritation phenomena of convulsions and tremor. In a recent case in the UK the pigs were off-color, showed anterior limb paralysis and were reluctant to rise and were therefore euthanased. Pigs were bright and keen to eat and drink.

Subacute viral encephalomyelitis (Talfan disease)
This is called Talfan disease in the United Kingdom, viral encephalomyelitis in North America and Australia, and poliomyelitis suum in Denmark. The subacute disease is milder than the acute form, and the morbidity and mortality rates are lower. The disease is most common and severe in pigs less than 2 weeks of age. Older sucking pigs are affected also, but less severely and many recover completely. Sows suckling affected litters may be mildly and transiently ill. The morbidity rate in very young litters is often 100% and nearly all the affected piglets die. In litters over 3 weeks old there may be only a small proportion of the pigs affected. The disease often strikes suddenly - all litters in a piggery being affected within a few days - but disappears quickly, subsequent litters being unaffected. Clinically, the syndrome includes anorexia, rapid loss of condition, constipation, frequent vomiting of minor degree, and a normal or slightly elevated temperature. In some outbreaks, diarrhea may precede the onset of nervous signs. Nervous signs...
appear several days after the illness commences. Piglets up to 2 weeks of age show hyperesthesia, muscle tremor, knuckling of the fetlocks, ataxia, walking backwards, a dog-sitting posture and terminally lateral recumbency, with padding convulsions, nystagmus, blindness, and dyspnea. The Dresden type of Teschovirus caused an ataxia and recumbency in a large group of pigs about 5 days after removal of the sows and housing in the production unit.11 Older pigs (4–6 weeks of age) show transient anorexia and posterior paresis, manifested by a swaying drunken gait, and usually recover completely and quickly. In the Japanese outbreak the pigs had at 40 days of age a flaccid paralysis of the hind limbs and became recumbent although they could move using their forelegs.10 After the initial group of affected piglets the disease disappeared.

Individual instances or small outbreaks of leg weakness with posterior paresis and paralysis in gilts and sows may also occur with this disease.

CLINICAL PATHOLOGY
Serology
Virus-neutralization and complement fixation are useful serological tests. Antibodies are detectable in the early stages and persist for a considerable time after recovery.

Detection of virus
Virus is present in the blood of affected pigs in the early stages of the disease, and in the feces in very small amounts in the incubation period before signs of illness appear, but brain tissue is usually used as a source of virus in transmission experiments. A nested–PCR has recently been described in which all 13 serotypes and field isolates were detected2 using three sets of primer pairs. It is more rapid and less time-consuming as a test than tissue culture and serotyping.

Virology
- one-half of mid-sagittally-sectioned brain, spinal cord including spinal ganglia, gasserian ganglion (LM)

In the recent German cases11 the virus was isolated from all the tissues examined but not from the blood. A technique using monoclonal antibodies has been described that can be used either as an immunofluorescent agent or for immunoelectron microscopy.13 New techniques using the reverse transcription polymerase chain reaction (RT-PCR) have recently been described that allow the distinction of both Porcine Teschoviruses (group I) and viruses of PEV1 and 2.14 In the recent Japanese description cytopathogenic agents were recovered from the tonsil, brainstem and cerebellar homogenates. The PCR products from these were then sequenced and the isolate confirmed as PTV. Isolation of virus is not easy and needs to be from the brain and spinal cord. There are no firm indications of when to take material and a good consistent site in the brain for isolation as yet.15

Samples for confirmation of diagnosis
- Histology – one-half of mid-sagittally-sectioned brain, spinal cord including spinal ganglia, gasserian ganglion (LM)
- Virology – one-half of mid-sagittally-sectioned brain, spinal cord (ISO, FAT)

The sporadic occurrence of the disease in a herd is usually an indication that infection is endemic. When outbreaks occur the possibility that introduction of a new strain has occurred should be considered. However, by the time clinical disease is evident it is likely that infection will be widespread and isolation of affected animals may be of little value. A closed herd policy will markedly reduce the risk of introduction of new strains into a herd, but there is evidence that they can gain access by indirect means. The sporadic nature of the occurrence of most incidents of porcine encephalomyelitis does not warrant a specific control program.

TREATMENT
There is no treatment.

REFERENCES
Sporadic bovine encephalomyelitis (SBE, BUSS DISEASE, TRANSMISSIBLE SEROSITIS)

Sporadic bovine encephalomyelitis (SBE) is associated with a chlamydia, and characterized by inflammation of vascular endothelium and mesenchymal tissue. There is secondary involvement of the nervous system, with nervous signs, in some cases.

ETIOLOGY

The disease is associated with Chlamydia (Chlamydia) pecorum.1-2 It resists freezing but is highly susceptible to sodium hydroxide, cresol, and quaternary ammonium compounds in standard concentrations. The chlamydia can be passaged in guinea-pigs and hamsters, and adapted to grow in the yolk sac of developing chick embryos.

EPIDEMIOLOGY

Occurrence

The disease has been reported only from the United States, Japan, and Israel but a provisional diagnosis has been made in Australia, where it is thought that the disease may have been present for some time, and in Canada, South Africa and Hungary. In the United States, it occurred most commonly in the midwestern and western states but there have been no reports of its occurrence for the last 30 years.

Sporadic cases or outbreaks occur in individual herds. Although the disease has not reached serious economic proportions in the endemic, there is some serological evidence that widespread subclinical infections occur.1

Only cattle and buffalo are affected, and calves less than 6 months of age are most susceptible. Other domestic and experimental species appear to be resistant. There is no seasonal incidence, cases appearing at any time of the year. A strong and apparently persistent immunity develops after an attack of the disease.

Prevalence of infection

Morbidity and case fatality rates

The occurrence is sporadic, but outbreaks have occurred resulting in severe loss due to both deaths of animals and loss of condition. Morbidity rates average 12.5% (5-50%), being highest in calves (25%) and lowest in animals over a year old (5%). Mortality rates average about 31% and are higher in adults than in calves. In affected herds a stage of herd immunity is reached when only introduced animals and newborn calves are susceptible.

Method of transmission

The method of spread is not known. Spread from farm to farm does not occur readily. On some farms only sporadic cases may occur, but on others one or two cases occur every year. In still other herds the disease occurs in outbreak form, with a number of animals becoming affected within a period of about 4 weeks. The epidemiology of SBE resembles in many ways that of bovine malignant catarh (BMC). The organism can be isolated from many organs, including liver, spleen and central nervous system, and from the blood, feces, urine, nasal discharges, and milk in the early stages of the disease. There is some evidence that the organism is eliminated in the feces for several weeks after infection.

PATHOGENESIS

The causative agent is not specifically neurotropic and attacks principally the mesenchymal tissues and the endothelial lining of the vascular system, with particular involvement of the serous membranes. Encephalomyelitis occurs secondarily to the vascular damage.

CLINICAL FINDINGS

Affected calves are depressed and in-active, but the appetite may be unaffected for several days. Nasal discharge and salivation with drooling are frequently observed. A fever is common (40.5-41.5°C, 105-107°F), and remains high for the course of the disease. Dyspnea, coughing, a mild catarhral nasal discharge, and diarrhea may occur. During the ensuing 2 weeks, difficulty in walking and lack of desire to stand may appear. Stiffness with knuckling at the fetlocks is evident at first, followed by staggering, circling, and falling. Opisthotonos may occur but there is no excitement or head-pressing. The course of the disease varies between 3 days and 3 weeks. Animals that recover show marked loss of condition and are slow to regain the lost weight.

CLINICAL PATHOLOGY

Hematology

In experimental cases, leukopenia occurs in the acute clinical stage. There is a relative lymphocytosis and depression of polymorphonuclear cells.

Detection of agent

The causative agent can be isolated from the blood in the early clinical phase, and can be used for transmission experiments in calves and guinea pigs, and for culture in eggs. Elementary bodies are present in the guinea-pig tissues and yolk-sac preparations.

Serology

Serological methods, including a complement fixation test for the detection of circulating antibody, are available although there is difficulty in differentiating antibodies to the chlamydia from those to the typical psittacosis virus.

NECROPSY FINDINGS

A fibrinous peritonitis, pleurisy and pericarditis, accompanied by congestion and petechiation are characteristic. In the early stages, thin serous fluid is present in the cavities, but in the later stages this has progressed to a thin fibrinous net covering the affected organs, or even to flattened plaques or irregularly shaped masses of fibrin lying free in the cavity. Histologically, there is fibrinous serositis involving the serosa of the peritoneal, pleural, and pericardial cavities. A diffuse encephalomyelitis involving particularly the medulla and cerebellum, and a menigitis in the same area are also present. Minute elementary bodies are present in infected tissues and in very small numbers in exudate. The necropsy findings are diagnostic for SBE and confirmation can be obtained by the complement fixation test or serum neutralization tests.

DIFFERENTIAL DIAGNOSIS

Clinically, the disease resembles other encephalitides of cattle. The epidemiology and pathogenesis resembles bovine malignant catarh (BMC), but the mortality rate is much lower, there are no ocular or mucosal lesions, and the serositis of SBE does not occur in bovine malignant catarh. A viral encephalomyelitis of calves (Kunjin virus) has been identified, but has not been associated with clinical signs of disease.

Listeriosis is usually sporadic and is accompanied by more localizing signs, especially facial paralysis and circling. Rabies may present a very similar clinical picture, but the initial febrile reaction and the characteristic necropsy findings as well as the epizootiological history of SBE should enable a diagnosis to be made. Lead poisoning can be differentiated by the absence of fever, the more severe signs of motor irritation, and the shorter course of the disease. Because of the respiratory tract involvement, SBE may be easily confused with pneumatic pasteurellosis, especially if outbreaks occur, but in the latter disease nervous signs are unusual and the response to treatment is good.
**TREATMENT**

Broad-spectrum antimicrobials control the agent in vitro. However, clinical results with chlortetracycline and oxytetracycline have been irregular, but may be effective if used in the early stages of the disease.

**CONTROL**

Control measures are difficult to prescribe because of lack of knowledge of the method of transmission. It is advisable to isolate affected animals. No vaccine is available.

**ETIOLOGY**

Louping-ill virus belongs to the genus *Flavivirus*, which is divided into eight groups, one of which is the tick-borne encephalitis group. Louping-ill is antigenically related to the tick-borne encephalitis viruses most of which cause disease in man but not in sheep. Louping-ill virus occurs in Great Britain and Norway, but similar disease occurs elsewhere and there is antigenic diversity between isolates from different geographic areas. Viruses that are closely related to loping-ill virus, and that cause very similar disease but in different regions of the world, include Russian spring-summer encephalitis virus, Turkish sheep encephalitis virus, Spanish sheep encephalitis virus, and Greek goat encephalomyelitis. In sheep, concurrent infection with the agent of tick-borne fever *Ehrlichia (Cytophaga) phagocytophila* enhances the pathogenicity of the virus.

**EPIDEMIOLOGY**

**Occurrence**

Geographic occurrence

Louping-ill was originally considered to be restricted to the border counties of Scotland and England but is now recognized as also occurring in upland grazing areas of Scotland, in Ireland, south west England, and in Norway; related viruses and disease occur in Spain, Bulgaria, and Turkey. The distribution of the disease is regulated by the occurrence of the vector tick *Ixodes ricinus*, which requires suitable hosts and a ground layer microclimate of high humidity throughout the year. In these areas, louping-ill can be a common infection and may be a significant cause of loss.

**Host occurrence**

Louping-ill virus can infect and produce disease in a wide variety of vertebrates including man, but predominantly sheep are affected because of their susceptibility and the fact that they are the main domestic animal species that graze the tick-infested areas.

While sheep (and red grouse) are the only animals that commonly develop clinical disease, *Ixodes ricinus* feeds on a number of different hosts and the adult tick requires a large mammalian host. As a consequence, seropositivity and occasional clinical disease occur in all other domestic species, especially goat kids, but also cattle, horses, pigs, and humans. Traditionally, pigs have not been free-ranged on upland tick-infested areas, but they are susceptible to experimental infection by all routes. Red deer (*Cervus elaphus*) and roe deer (*Capreolus capreolus*) are hosts for the tick in Scotland, and the elk (*Alces a. alces*) may be in Sweden. Infection in these areas is usually sub-clinical; however, when these animals are subjected to the stress of captivity, clinical illness is more likely to occur. This may be important to commercial deer farmers.

**Transmission**

**Tick transmission**

The reservoir for the disease and the major vector is the three host tick *I. ricinus*, which requires a single blood meal at each stage of development. The tick feeds for approximately 3 weeks every year and completes its life cycle in 3 years. The larval and nymphal stages will feed on any vertebrate but the adult female will engorge and mate only on larger mammals. The tick becomes infected by feeding on a viremic host and the virus translocates to the salivary gland of the subsequent stage to provide a source of infection at feeding in the following year. Transstadial transmission of the virus occurs, but transovarial transmission does not, and thus only the nymph and adult ticks are capable of transmitting the disease. The activity of the tick is seasonal. The tick is active at temperatures between 7 and 18°C, and most ticks feed in the spring with peak activity dependent upon the latitude and elevation of the pasture but generally occurring in April and May. In some areas there is a second period of activity of a separate population of *I. ricinus* in the autumn during August and September. While infected ticks can transmit the infection to a large number of vertebrate hosts, only sheep, red grouse (*Lagopus scoticus*), and possibly horses attain a viremia sufficient to infect other ticks and act as maintenance hosts.

Grouse amplify the virus, deer amplify the vector and hares (*Lepus timidus*) amplify both. Infection in red grouse is accompanied by a high mortality, and the louping-ill virus is essentially maintained in an area by a sheep–tick cycle and hare tick cycle.

**Non-tick transmission**

Although the major method of spread is by the bites of infected ticks, spread by droplet infection is of importance in man, and the infection can be transmitted in animals by hypodermic needle contamination and other methods. The virus is not very resistant to environmental influences and is readily destroyed by disinfectants. Pigs fed the carcasses of sheep that had died of louping-ill become infected with the louping-ill virus. The virus is excreted in the milk of experimentally infected female goats, and infects suckling kids to produce an acute disease. Virus is also excreted in the milk of ewes during the acute stages of infection but, paradoxically, does not result in the transmission of the infection to lambs. Grouse can be infected by eating infected ticks and this is considered a major mechanism of infection for grouse.

**Host and environmental risk factors**

The epidemiology of disease is dictated by the biology of the tick, and disease is seasonal with occurrence during spring when the ticks are active. The prevalence of infection, as measured by seropositivity, is high in areas where the disease is enzootic. In these areas, the annual incidence of disease varies but there are cases every year and they occur predominantly in yearlings and in lambs. In enzootic areas, the majority of the adult sheep have been infected and are immune. Colostral immunity from these ewes will protect their lambs for approximately 3 months and these lambs are resistant to infection during the spring rise of the ticks. Ewe lambs that are retained in the flock are susceptible to infection at the second exposure the following spring.

The proportion of infected animals that develop clinical disease in any year is estimated to vary from 5 to 60% and
The initial viremia that occurs with infection declines with the emergence of serum antibody and virus is no longer present in the blood at the onset of clinical signs. Hemagglutination inhibition, complement-fixing and neutralizing antibodies can be detected in the serum of recovered animals. Hemagglutination inhibition and complement-fixing antibodies are relatively transient, but neutralizing antibodies persist. Hemagglutination inhibition is usually not considered because of the zoonotic risk.

**Necropsy Findings**

No gross changes are observed. Histologically, there are perivascular accumulations of cells in the meninges, brain and spinal cord, with neuronal damage most evident in cerebellar Purkinje cells and, to a lesser extent, in the cerebral cortex. Louping-ill virus can be demonstrated in formalin-fixed tissues by the avidin-biotin-complex immunoperoxidase technique.4

**Samples for confirmation of diagnosis**

- **Virology** — chilled brain, halved mid-sagittally (VI)
- **Histology** — fixed brain, other half (LM, IHC).

**DIFFERENTIAL DIAGNOSIS**

The disease is restricted to areas where the vector tick occurs and this allows or denies a possible diagnosis.

- In lambs, the disease has clinical similarities with delayed swayback, spinal abscess, and some cases of tick pyemia. Spinal abscess occurs shortly after a management procedure such as docking or castration or with tick pyemia; it has a longer clinical course, is commonly present at C7–T2, and can be established by radiographic examination. Tick pyemia can also occur in flocks that have louping-ill and the determination of the contribution of each disease to flock mortality relies on clinical, epidemiological, and postmortem examination.
- In yearlings, the disease has similarities to spinal ataxia due to trauma, to gid (Coenuris cerebralis), and to the early stages of polioencephalomacia.
- In adults, the disease in sheep bears resemblance to some stages of scrapie, tetanus, hypocalcemia, hypomagnesemia, pregnancy toxemia, and ovine kangaroo gait.
TREATMENT
An antiserum has been used and affords protection if given within 48 hours of exposure, but is of no value once the febrile reaction has begun. It is not available commercially. Animals with clinical disease should be sedated if necessary during the acute course of the disease, and should be kept in a secluded and dark area with general supportive care.

CONTROL
The prevention of louping-ill requires either the prevention of exposure of sheep to tick-infested pastures or the immunization of animals prior to exposure. Immunization has been the traditional approach.

Historically, a formalized tissue vaccine derived from brain, spinal cord, and spleen was used, and provided excellent immunity in enzootic areas. The vaccine was not without risk for persons manufacturing it and at one stage led to an outbreak of scrapie where the vaccine was prepared from sheep incubating the disease. Currently, vaccination is with a formalin-killed tissue culture derived vaccine where the virus has been concentrated ten-fold by methanol precipitation or ultrafiltration. The vaccine is administered in an oil adjuvant. A single dose of this vaccine will give protection for at least 1 year and possibly up to 3 years, and has been shown to give excellent results in field trials. The vaccine is used in the autumn, or in the early spring 1 month before the anticipated tick rise, in all ewe lambs that will be held for flock replacements. Vaccination of pregnant ewes twice in late pregnancy is recommended to insure adequate passive immunity to the lambs via the colostrums. A recombinant vaccine has also been shown to offer protection against infection.

The limited geographical occurrence of this disease and commercial economics has, and may, restrict the availability of vaccines. Consequently tick control, or the elimination of infection from pastures, may be the required approach in the future. The intensity of tick infestation of pastures can be reduced by influencing the microclimate that they require for survival. In some areas this can be achieved by ditching and drainage of the pastures. The control of the causative tick using acaricides is detailed in the section on ticks and provides some protection against disease.

Epidemiological, modeling, and experimental studies indicate that sheep and red grouse and hares are the only maintenance hosts for the virus and this, coupled with the fact that there is no transovarial transmission of the virus in the tick, offers a potential method for eradication of the infection from an area.

This approach, the elimination of grouse and hares, would be radical and would require an economic assessment of its benefits--cost in relation to alternate methods of control.

CAPRINE ARTHRITIS ENCEPHALITIS (CAE)

**ETIOLOGY**
Caprine arthritis encephalitis (CAE) viruses are non- oncogenic retroviruses belonging to the subfamily Lentivirinae. The causal viruses are not identical but are of a single virus type, and genetically distinct isolates may have different virulence. Antigenic drift is common and may facilitate the persistence of the virus in the host and the development of disease. There is a high degree of relatedness with the lentivirus associated with maedi-visna and ovine progressive pneumonia in sheep; the ovine and caprine lentiviruses share nucleotide homology and serological properties, and there is a similarity in the disease pathogenesis.

**EPIDEMIOLOGY**

**Geographic occurrence**
There is serological evidence of infection in most areas of the world, including Europe, the United Kingdom, North America, Africa, Arabia, Australia, New Zealand, and South America. While there is sampling bias, one global study indicates that there are marked differences in prevalence between countries and that the prevalence is noticeably less in developing countries that have not had importations of dairy-type goats from North America or Europe. Other countries, such as New Zealand, have a low prevalence with a distribution related to exotic importations.

There may also be variation in seroprevalence within countries. In the United States, the prevalence of infection in goats in the western and middle parts of the country is approximately 50% of all goats tested, which is about twice that in the eastern and Rocky Mountain areas. Herd seroprevalence is greater than 60% in all regions. The seroprevalence within herds shows clustering, with most herds falling into either high or low seroprevalence groups. There are area differences in age prevalence of seropositivity, with some surveys showing no difference and others showing an increasing prevalence with increasing age.

Clinical disease is much less common than infection and the annual incidence of disease in heavily infected flocks is usually low and approximates 10%.

**Host risk factors**

**Breed**
All breeds are susceptible to infection but several studies have recorded apparent differences in breed susceptibility, which may reflect differences in management practices such as feeding practices of colostrum and milk, or genetic differences in susceptibility.

There is a higher prevalence of seropositive goats in family-owned farms as compared to institutional herds, which might reflect a greater movement of goats among the former.
Age
There is no age difference in susceptibility to experimental infection. Some herds show similar seroprevalence across age groups, while others show an increasing seroprevalence with increasing age. These differences probably reflect differences in management between herds and differences in the relative importance of the mechanisms of transmission between herds. Increasing prevalence with age reflects management systems that increase the risk of acquiring infection from horizontal transmission. Leukoencephalomyelitis occurs predominantly in young kids and arthritis in older goats.

Method of transmission
Greater than 75% of kids born to infected dams may acquire infection, and infection can potentially be transmitted to them by several routes. Infection can also occur in older goats by different routes.

Colostrum and milk
Observation of the natural disease and experimental studies indicate that the primary mode of transmission is through the colostrum and milk. The presence of antibody in colostrum does not prevent infection. The virus can be isolated both from the cells in the milk and from cell-free milk from infected dams; kids born of non-infected dams but fed colostrum and/or milk from infected dams become infected. A single feeding of infected milk can be sufficient to infect a kid. Conversely, the risk of infection is much lower in kids that are removed from the doe immediately after birth and reared on pasteurized milk, and some can be reared free from infection.

Other perinatal transmission
It is probable that intrauterine infection can occur, but this appears to be of infrequent occurrence and not of significance to the control of the disease. The disease can be transmitted by contact both during and following the perinatal period, and perinatal transmission is important in the epidemiology of the disease. Perinatal transmission could result from contact with vaginal secretions, blood, saliva or respiratory secretions but the relative importance of these is not known.

Contact transmission
Horizontal transmission occurs at all ages and older goats can be infected by oral challenge with virus. Contact transmission will result in the spread of the disease when an infected animal is introduced into an infection-free herd and has been one cause of spread in countries where the infection has been introduced with imported animals.

Prolonged co-mingling of uninfected with infected animals is likely to promote horizontal transmission.

Other routes
Milk contains free virus and virus-infected cells and shared milking facilities increase the risk of cross-infection. Possibly this results from the transfer of infected cells in milk during the milking process. Iatrogenic and venereal transmission are possible but appear of limited significance.

Experimental reproduction
Arthritis and mastitis have been reproduced by oral, intravenous and intraarticular challenge with virus; however, pneumonia is not a feature of the experimental disease. Leukoencephalomyelitis in young lambs can be reproduced by intracerebral challenge but this form of the disease has not been reproduced by more natural challenge routes. Strains of the virus can be neuroadapted by passage and show increased neurovirulence but not neuroinvasiveness, suggesting that these are separate characteristics.

The relatedness of the caprine and the ovine lentiviruses is evident with experimental infections. Experimentally, infection with the caprine virus has been transferred to lambs by feeding them infected colostrum or by injection. Experimental infection of lambs is followed by viremia and seroconversion, but some strains of the virus produce no clinical or histopathological evidence of disease. Kids have been similarly infected with the maedi virus. The arthritic form of the disease has been produced experimentally in Cesarlean-derived kids injected with virus isolated from the joints of infected goats. Despite these experimental cross-species transmissions, there is no evidence for cross-species transmission in the field.

Economic importance
There is a high prevalence of infection in many countries, and several of these have opted for national or breed-associated control programs. There is a higher cull rate in infected herds, as high as 5–10% of goats are culled each year for arthritis, and affected animals cannot be entered for show. Seropositive herds have a higher incidence of disease.

There are conflicting reports on the effect of infection on productivity in goat herds but seropositive goats are reported to have significantly lower milk production, a reduced length of lactation, lower 300-day yields of milk, and impaired reproductive performance.

PATHOGENESIS
Animals infected at birth remain persistently infected for life, although only a proportion develop clinical disease. The virus persistently infects a proportion of cells of the monocyte–macrophage type, and the expression and shedding of virus occurs as infected monocytes mature to macrophages. Disease is the result of inflammation resulting from the reaction of the host immune system to expressed virus. The development of neutralizing antibody does not arrest viral replication because of the continual expression of antigenic variants of the virus with differing type-specific neutralization epitopes. However, the immune complexes are believed to be the basis for the chronic inflammatory changes in tissues. Goats that are vaccinated with the virus develop more severe clinical disease following challenge than non-vaccinated controls. The lesions are lymphoproliferative in nature and the virus causes a multisystem disease syndrome, which primarily involves synoviallined connective tissue causing chronic arthritis, the udder causing swelling and hardening of the glands, with or without mastitis, and the lungs causing a chronic interstitial pneumonia.

A retrovirus infection, detected by electron microscopy and the presence of reverse transcriptase activity is suspected as the cause of an immunodeficiency syndrome in llamas characterized by failure to thrive, anemia, leukopenia, and recurrent infection.

CLINICAL FINDINGS

Joints
Arthritis occurs predominantly in adult goats and is a chronic hyperplastic synovitis, which is usually noticeable only in the carpal joints, giving rise to the lay term of big knee. Tarsal joints may also be clinically affected. The onset may be insidious or sudden, and unilateral or bilateral. If the goat is lame in the leg, lameness is not severe. Affected goats may live a normal life span but some lose weight gradually, develop poor hair coats, and eventually remain recumbent most of the time with the consequent development of decubitus ulcers. Dilatation of the atlantal and supraspinous bursae occurs in some cases. The course of the disease is long, lasting several months. The arthritis may be accompanied by enlargement and hardening of the udder and by interstitial pneumonia, although this may be clinically inapparent. There can be herd and area differences in the clinical expression of the disease, and in some outbreaks in Australia pneumonia has been a prominent feature.

Radiographically, there are soft tissue swellings in the early stages, and calcification of periarticular tissues and osteophyte production in the later stages.
Quantitative joint scintigraphy provides an accurate non-invasive method for assessing the severity of the arthritis in a live animal.22

Brain
Leukoencephalitis occurs primarily in kids from 1 to 5 months of age. The syndrome is characterized by unilateral or bilateral posterior paresis and ataxia. In the early stages, the gait is short and choppy, followed by weakness and eventually recumbency. In animals that are still able to stand, there may be a marked lack of proprioception in one hindlimb. Brain involvement is manifested by head tilt, torticollis and circling. Affected kids are bright and alert, and drink normally. Kids with unilateral posterior paresis usually progress to bilateral posterior paresis in 5–10 days. The paresis usually extends to involve the forelimbs so that tetraparesis follows. Most kids are euthanized. The interstitial pneumonia that commonly accompanies the nervous form of the disease is usually not sufficiently severe to be obvious clinically.

Udder
Indurative mastitis, or hard bag, is often initially detected a few days after kidding. The udder is firm and hard but no milk can be expressed. There is no systemic illness and no bacterial mastitis. Recovery is never complete but there may be some gradual improvement.

CLINICAL PATHOLOGY
The synovial fluid from affected joints is usually brown to red-tinged, and the cell count is increased up to 20,000 μL with 90% mononuclear cells. The cerebrospinal fluid may contain an increased mononuclear cell count. There is a reduction in monocytes in peripheral blood, a decrease in the number of CD4+ lymphocytes, and a lower or inverted CD4:CD8 ratio.23

Serological testing
For the live animal there are a number of test systems available whose sensitivity and specificity varies.24 Agar gel immunodiffusion test (AGID) is widely used for detection of infection. Seropositive animals are considered to be infected with the virus, maternal antibody is lost by approximately 3 months of age, a seropositive test in a goat older than 6 months of age is considered evidence of infection and most, but not all, animals have a persistent antibody response and remain seropositive for life.

A negative test does not rule out the possibility of infection. There may be a considerable delay between infection and the production of test reactive antibody. It is possible that in some infected goats there is insufficient virus expression to lead to an antibody response.22,25

A competitive-inhibition ELISA that detects antibody to the surface envelop of the virus has very high sensitivity and specificity and may aid considerably in the determination of the infection status for animal movement.29 Tests with possibly greater sensitivity and/or specificity are described,26 but are not generally available.

Identification of the presence of CAE is usually provided by isolation of the virus from tissue explants into tissue culture.1 PCR techniques can be used to detect the presence of antigen.26,30

NECROPSY FINDINGS
At necropsy of a case of the arthritic form there is emaciation and chronic polyarthritis. Typically, degenerative joint disease affects most of the joints of animals submitted for necropsy. Peripheral tissues are thickened and firm and there is hyperplasia of the synovium. The local lymph nodes are grossly enlarged and a diffuse interstitial pneumonia is usually present. Mammary glands are frequently involved although gross changes are restricted to induration and increased texture. Microscopically, lymphoplasmacytic infiltrates of the interstitial tissues of mammary gland, lung, and synovium are characteristic. In the neural form the diagnostic lesions are in the nervous system and involve the white matter, especially of the cervical spinal cord and sometimes the cerebellum and the brain stem. The lesion is a bilateral, non-suppurative demyelinating encephalomyelitis. The infiltrating mononuclear leukocytes tend to be more numerous in the periventricular and subpial areas. There is usually also a mild, diffuse, interstitial pneumonia in this form of the disease. In some cases, a severe lymphoplasmacytic interstitial pneumonia with extensive hyperplasia of type II pneumocytes can occur in the absence of neurologic disease.

Culture of the virus is difficult but can be attempted. A variety of nucleic acid recognition tests, including in situ hybridization and PCR have been developed.36 An immunohistochemical technique for detection of the virus has also been reported.37 For most cases, confirmation of the diagnosis is based on the characteristic microscopic lesions, preferably supported by antemortem serologic results.

Samples for confirmation of diagnosis
- Histology – formalin-fixed lung, bronchial lymph node, mammary gland, synovial membranes, one-half of mid-sagittally-sectioned brain, spinal cord (LM, IHC)
- Serology – heart blood (ELISA, AGID)
- Virology – lung, synovial membrane, mammary gland, hindbrain (PCR, VI).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the arthritic form of the disease includes the other infectious arthropides, such as those associated with mycoplasma and chlamydia.

Leukoencephalitis must be differentiated from:
- Swine dysentery due to copper deficiency
- Spinal abscess
- Cerebrospinal nematodiasis
- Listeriosis
- Polioencephalomalacia.

TREATMENT
There is no treatment likely to be of value for any form of the disease.

CONTROL
A measure of control can be achieved by testing the herd every 6 months, and segregating or culling of seropositive animals. More complete control is dependent on preventing/minimizing perinatal transmission of infection to the kid, particularly colostrum and milk transmission, coupled with identifying infected animals and maintaining them physically separated from the non-infected animals or culling them from the herd.

Prevention of perinatal transmission
Early recommendations for control concentrated on control of milk transmission but it is now recognized that this must be coupled with segregation. Newborn kids should be removed from the dam immediately at birth. There should be no contact with the dam, and fetal fluids and debris should be rinsed off the coat.

Heat-treated goat colostrum or cow colostrum should be fed, followed by pasteurized milk or a commercial milk replacer. The kid should be segregated from the doe and other infected animals. There is a significant difference in subsequent seroconversions in herds that feed pasteurized colostrum and milk between those that segregate the kids at birth and for rearing and those that do not.7

Test and segregate/cull
Animals over 3 months of age should be tested by AGID every 6 months, and seropositive animals should be segregated or culled from the herd. The interval between infection and seroconversion varies between goats, and the optimal interval for testing has not been determined. More frequent testing may be required for large herds with high seroprevalence.7 Segregation of seropositive and seronegative goats is essential, as
horizontal spread in adult goats is important in maintaining and increasing infection rates in some herds and even a brief contact time can allow transmission.\textsuperscript{28} Seropositive goats should be milked after seronegative goats where culling is not practised. The use of common equipment should be avoided.

Several countries have programs for herd accreditation of freedom from infection. The stringency of these schemes varies and they may be governmental or breed society accreditation programs. In general, they require that all adults in the herd test negative on two herd tests at a 6-month interval. There are also restrictions on the movement and purchase of animals, and periodic serological surveillance.

**REVIEW LITERATURE**

**REFERENCES**

**VISSA**

**Etiology** Neurovirulent strains of maedi-visna virus, a lentivirus

**Epidemiology** Occurs in association with maedi but endemic visna only recorded in Iceland

**Clinical findings** Afebrile disease with insidious onset. Progressive ataxia and wasting, long clinical course

**Clinical pathology** Plecytosis and elevated protein, virus, virus proteins, and antiviral antibody in cerebrospinal fluid

**Lesions** Charly demyelinating encephalomyelitis

**Diagnostic confirmation** Histology, demonstration of virus

**Treatment** None

**Control** As for ovine progressive pneumonia

**ETIOLOGY**
Visna is associated with an ovine lentivirus and is the neurological manifestation of maedi-visna disease. Ovine lentivirus consists of a variety of strains that vary in their ability to infect target cells and cause disease. There are neurovirulent and non-neurovirulent strains, and neurovirulence can be enhanced by intracerebral passage of virus. Visna usually occurs in conjunction with maedi lesions in the lungs, and 10–18% of sheep with maedi have histological lesions of visna in the brain.\textsuperscript{3,4}

**EPIDEMIOLOGY**
Visna is a disease of sheep and rarely of goats. Visna was originally recorded in Iceland and was a significant cause of death in the epizootic of maedi-visna that occurred in that country. It always occurred in association with maedi and was generally of sporadic occurrence and lesser importance than the pulmonary manifestation of the infection although in some flocks it was the major manifestation of the complex. Visna has not been seen in Iceland since 1951 and maedi-visna has since been eradicated from Iceland. Despite the widespread occurrence of maedi-visna or ovine progressive pneumonia in many countries visna is a very uncommon disease and a significant occurrence of clinical disease has seldom been recorded in countries other than Iceland.\textsuperscript{4–6} The reason for this is not known but might be due to an increased susceptibility of the Icelandic breed of sheep to the neurological form of the disease, or to differences in maedi-visna virus strain neuroinvasiveness and neurovirulence. Maedi-visna virus was first reported in Britain in the late 1970 and the clinical expression since that time had largely been maedi occasionally with coexistent visna. However, recently there has been the occurrence of visna without evidence of respiratory disease suggesting that a neurotropic strain might be emerging in that country.\textsuperscript{9}

**Experimental transmission**
Experimental transmission of the infection and the disease is effected by intracerebral inoculation and spread occurs from this to commingled sheep.\textsuperscript{10} The incubation period and the course of the disease are very long; clinical signs may not appear for 2 years after experimental inoculation.

**PATHOGENESIS**
The virus infects cells of the monocyte-macrophage lineage and replicates its RNA genome via a DNA intermediate provirus which is integrated into the chromosomal DNA of the host cell. Replication is limited and does not proceed beyond the synthesis of provirus in most cells. Persistent production of viral antigen results in lymphocytic hyperplasia. Although age has little effect on the development of disease, fetal and neonatal lambs have slightly greater permissiveness for replication of the virus. However, free infectious virus is present only in small quantities, but over very long periods. The genotype of the host is important and all breeds of sheep do not react to the same degree. Thus, Icelandic sheep react much more severely than English breeds.

There are two basic lesions, an inflammatory lesion which is not related to the occurrence of nervous signs, and a focal demyelination in the brain and spinal cord, the occurrence of which is related to the appearance of paresis.\textsuperscript{11} Experimental immunosuppression greatly reduces the severity of lesions, by suppressing the cellular proliferative response without suppressing the growth of the virus and post-infection immunization enhances the severity of experimental visna.\textsuperscript{12} Viral nucleic acid and proteins are present in oligodendrocytes, and demyelination is believed to result from the direct effect of the virus on these cells as well as being the result of an inflammatory response provoked by the presence
of these antigens.13

**CLINICAL FINDINGS**

The disease has an insidious onset and the early clinical signs include lagging behind the flock because of ataxia and body wasting. The body wasting and the hindlimb ataxia are progressive. Affected animals show hypermetria and may stumble or fall as they traverse uneven ground or when making sudden turns. There is no fever, and a normal appetite and consciousness are retained. Additional signs include severe tremor of the facial muscles, and knuckling of the distal limbs so that the animal stands on the flexed tarsi. Some animals may show a head tilt. Aimless wandering and blindness occur in some sheep.7

The clinical picture is not unlike that of scrapie without the pruritus. During the course of the disease, periods of relative normality may occur. Affected animals may show clinical signs for several months before final paralysis necessitates slaughter. The disease is always fatal. The clinical syndrome in goats is the same as that for sheep.

**CLINICAL PATHOLOGY**

There is an increased number of mononuclear cells in the cerebrospinal fluid, an elevated protein, and positive Pandy test.6,8 The pleocytosis is variable during the course of the disease.4 Virus, virus antigen, and antibody are also demonstrable in cerebrospinal fluid.3 Serological tests are detailed under the section on ovine progressive pneumonia.

**NECROPSY FINDINGS**

Muscle wasting and an interstitial pneumonia may be visible but there are no gross changes in the central nervous system. The characteristic histological lesion is patchy, demyelinating encephalomyelitis. The inflammatory infiltrate is predominantly comprised of lymphocytes and macrophages. Demyelination occurs in the white matter of the cerebrum and cerebellum, and in the spinal cord. The histological character of the lung is typical of ovine lentivirus-associated pneumonia. Isolation of the virus is difficult. Typical neural lesions and a positive serological titer usually suffice for confirmation of the diagnosis. Immunohistochemical tests and PCR-based assays have been successfully employed to confirm this lentiviral infection in lung, mammary gland,14 and even third eyelid15 but the use of these tests to confirm the infection in CNS tissues is not well documented.

**Samples for confirmation of diagnosis**

- **Histology** – fixed spinal cord, one-half of midsagittally-sectioned brain,
- **lung**, **mammary gland**, **joint synovium (IHC, LM)**
- **Serology** – heart blood serum (AGID, ELISA)
- **Virology** – chilled brain, spinal cord, lung, mammary gland (PCR, ISO).

**DIFFERENTIAL DIAGNOSIS**

Visna is a sporadic disease of mature sheep with an insidious onset of muscle wasting, progressive ataxia and having a long clinical course. These characteristics differentiate it from other diseases of sheep manifest with ataxia. Differentials include:

- **Scrapie**
- **Delayed organophosphate toxicity**
- **Cerebrospinal nematodiasis**
- **Segmental axonopathy (Murrurundi disease).**

**TREATMENT AND CONTROL**

There is no treatment. Visna is a rare disease. Iceland achieved control by slaughter eradication, other control procedures are those for ovine progressive pneumonia.

**REFERENCES**

**ETIOLOGY**

The causal agent, border disease virus (BDV), is a pestivirus in the family Flaviviridae. Four different species or genotypes have been identified in the pestivirus genus, bovine virus diarrhea virus (BVDV) types 1 and 2, classical swine fever virus (CSFV) and border disease virus (BDV). Isolates from border disease predominantly fall within the BDV genotype but sheep and goat isolates also fall in the BVDV genotypes.1,2 It is proposed that the BDV genotype can be divided into BDV-1, BDV-2, BDV-3 based on host origin and genetic and antigenic characteristics.3

Strains of BDV have differing pathogenicity, and variations in pathogenicity also result from interactions between the virus and different host genotypes, specifically between different breeds of sheep.1,4 Persistent infections in sheep are associated with non-cytopathic strains of virus. An isolate of BDV is thought to have caused a leukopenic enzooticosis in sheep and growing lambs in the Aveyron region of France (Aveyron disease). The disease caused high mortality in sheep in this region in 1984 but has not occurred subsequently.5

**EPIDEMIOLOGY**

**Occurrence**

Border disease was originally described in the border country between England and Wales. It has subsequently been reported from most of the major sheep-producing countries6,7 and probably occurs in all. The disease occurs naturally primarily in sheep and occasionally in goats. The prevalence of infection is much higher than the incidence of clinical disease as the latter only occurs when there is infection during pregnancy.

Studies on seroprevalence vary in design but suggest that pestivirus infections in sheep and goats are less common than in cattle and that there are considerable differences in seroprevalence between different geographical areas and flocks. Flock seroprevalence in different regions or countries generally falls within the range of 5 to 50%. The prevalence of seropositive females within positive flocks is influenced by age with a lower seroprevalence in sheep 4 to 8 months of age than in older sheep. Seroprevalence is higher in flocks with persistently infected sheep but there can still be a
significant proportion of seronegative sheep present in a flock containing persistently infected sheep.\textsuperscript{7}

**Source of infection**

Infection can be introduced into a flock with the purchase of persistently infected replacement sheep. Persistently infected sheep excrete virus in nasal secretions, saliva, urine and feces,\textsuperscript{2,6} and provide the major source of infection. A proportion of persistently infected sheep may survive to adulthood and may breed successfully to produce further persistently infected sheep.\textsuperscript{5} However, the breeding efficiency of persistently infected sheep is poor and the probability of establishing lines of persistently infected sheep appears less than with the equivalent infection in cattle.\textsuperscript{6,9}

Virus is also present in the placenta and fetal fluids at the birth of persistently infected lambs, and in the products of abortions resulting from infection with the virus in early pregnancy. In flocks where there is a long lambing period it is possible that this could provide a source for clinical disease in late lambing ewes. Field observations suggest that transmission during the lambing period is limited.

Calves persistently infected with BVDV can infect sheep,\textsuperscript{10} and in countries where pregnant sheep and cattle are housed in close proximity during the winter this can be an important source of infection for outbreaks of border disease. In some countries it appears the major source and recent studies in both Northern Ireland and the Republic of Ireland suggest that cattle are the primary source of infection for sheep in those countries.\textsuperscript{11,12} In contrast BDV is the predominant ovine pestivirus in Great Britain and New Zealand.\textsuperscript{13}

There is also evidence that bovine strains are important in goat infections.\textsuperscript{1,14}

Free-living deer are also a potential source of infection. Outbreaks of disease are also recorded as the result of vaccinating pregnant goats with a pestivirus contaminated Orf vaccine.\textsuperscript{15}

**Transmission**

Transmission is by sheep-to-sheep contact and experimental transmission has been effected with both oral and conjunctival challenge.\textsuperscript{2,6}

The speed of spread of infection in a susceptible flock will vary with the management, and will be facilitated by factors such as close contact at mating time or gathering for any purpose. There is an increased risk for explosive outbreaks of border disease where animals are housed in early pregnancy.

**Host risk factors**

Border disease may occur as an outbreak or as a sporadic disease. When infection is introduced into a susceptible flock in early pregnancy, an outbreak with infertility, abortion and congenital disease in lambs from all ages of ewes is likely. Subsequently, older sheep in the flock will have immunity and disease is only common in introduced sheep and maiden ewes. Persistently infected ewes have reduced fertility but will give birth to congenitally affected lambs throughout their breeding life.\textsuperscript{6,9} The disproportional occurrence of outbreaks of clinical disease in certain breeds suggests that these breeds have higher rates of persistently infected individuals.

**Experimental reproduction**

Border disease is readily reproduced by the experimental infection of pregnant ewes prior to 80 days gestation and can be effected by oral, conjunctival and parenteral challenge.\textsuperscript{6,9} Experimental disease can be produced with both BDV and BDV strains.

The following have been produced experimentally, although there are strain differences in clinical and pathological manifestations:

- Placentitis
- Abortions
- Mummified fetuses
- Congenital malformations, including hydrocephalus, porencephaly, cerebellar hypoplasia and dysplasia, and arthrogryposis
- Fetal growth retardation
- Hypomyelination
- Birth of weak lambs with nervous disorders
- A hairy birthcoat.

Experimental infections of pregnant cows with BDV results in similar defects with placentitis, mummification and abortion of fetuses, intrauterine growth retardation with abnormal osteogenesis, and hypomyelination.

The disease has also been produced experimentally in goat kids by inoculation of pregnant goats but there are no abnormalities of hair coat, and embryonic mortality and abortion are more common than in the experimental disease in ewes.\textsuperscript{8,9}

**Economic importance**

The effect of infection varies with the immune status of the flock and whether infection occurs during pregnancy. In fully susceptible flocks, abortion and neonatal lamb loss resulting from infection can be 25–75% of the expected lamb crop depending upon the strain of the virus.\textsuperscript{3} An assessment of the economic losses due to infertility, abortion, neonatal losses, and low carcass weight indicate that an outbreak of border disease can result in a potential reduction of income in excess of 20%.\textsuperscript{17}

**PATHOGENESIS**

**Non-pregnant sheep**

In adolescent and adult non-pregnant sheep, infection and viremia are subclinical. The IM inoculation of immunocompetent lambs with BDV results in a mild transient disease and a subsequent reduction in growth rate, but no gross or microscopic lesions.

**Pregnant sheep**

When BDV infects susceptible pregnant ewes the virus infects the placenta to produce an acute necrotizing placentitis and it subsequently invades the fetus. This may result in early embryonic death, abortion and stillbirth, the birth of lambs with malformations and/or neurological abnormalities, the birth of small weak lambs which are immunosuppressed, or the birth of lambs with no clinical abnormality. The ultimate outcome of the infection depends on the age of the fetus, the properties of the strain of the virus, the dose of the virus, the genotype of the host, and the ability of the fetus to respond to the virus. **Fetal age** at the time if infection is most important, as it is the determinant of the ability of the fetus to mount an immune response to the infection.\textsuperscript{2,6,9,38} Immune competence to the virus in sheep develops between approximately 61 and 80 days of gestation.

Infection in early pregnancy

**Fetal death** occurs when there is infection of the fetus with virulent strains prior to the development of immune competence and uncontrolled viral replication. Premature death is more likely to follow infections in early pregnancy but is recorded with infections from 45 to 72 days of gestation.

**Persistent infections** occur in lambs that survive infection in early pregnancy prior to the development of immune competence and result from maternal infections between 21 and 72 days of gestation but never later.\textsuperscript{19} The virus is present in all organs, and lambs born persistently infected will remain so for their lifetime, with few exceptions; persistent infections have been recorded to at least 5 years of age.\textsuperscript{9}

Most persistently infected sheep are unable to produce specific antibody to BDV but some show intermittent sero-reactivity with low antibody levels or occasionally undergo frank seroconversion.\textsuperscript{19} The humoral response to other pathogens and antigens is normal. However, cell-mediated immunity is compromised, with change in T-cell populations and a deficiency in lymphocyte function.\textsuperscript{20} Persistently infected lambs are more susceptible to intercurrent disease and commonly die before reaching maturity.
Hypomyelogenesis occurs in persistently infected lambs and resolves spontaneously in lambs that survive to the age of 6 months. Most of these lambs exhibit neurological dysfunction at birth, varying from a continuous light tremor to tonic-clonic contraction of the skeletal muscles involving the whole body and head (shakers).

**Thyroid.** A deficiency of the thyroid T₃ and T₄ hormones has been detected in lambs affected with border disease and may be the basic cause of the amyelination. The enzyme 2',3'-cyclic nucleotide-3'-phosphohydrolase is associated with normal myelination and depends upon normal amounts of thyroid hormone. The deficiency in thyroid hormones may also result in the reduced rate of weight gain that occurs in infected lambs. Other studies suggest a direct infection of oligodendroglia with the virus as the cause of the defective myelination.

**Fleece abnormality** also occurs in persistently infected lambs and results from an enlargement of the primary hair follicles and a concurrent reduction in the number of secondary follicles. The resulting hairiness is due to the presence of large medullated primary fibers BDV appears to have no effect on the skin and birthcoat of coarse-fleeced breeds of sheep or on goats.

**Intrauterine growth** retardation is a common feature of infection with BDV and is initiated shortly after infection. Deformities of the skeleton include abnormally shortened long bones, a reduction in crown–rump length and the long axis of the skull, which results in lambs appearing more compact and short-legged than normal (goat lambs). In the long bones there is evidence of growth arrest lines and disturbed osteogenesis and ossification.

Some persistently infected lambs have neither nervous signs nor abnormalities of the fleece and are phenotypically normal. This limits the value of identification of infected lambs based on the presence of clinical abnormality at birth.

In mid-pregnancy
When fetal infection occurs during the period of development of the ability to mount an immune response (between approximately 61 and 80 days of gestation) the effect is variable. Some fetuses infected at this stage respond with a severe inflammatory process in the CNS with nodular periarthritis, necrosis, and inflammation of the germinal layers of the brain. Resultant lesions are hydranencephaly, cerebellar dysplasia and multifocal retinal atrophy; such lambs exhibit behavioral abnormalities and more severe neurological disease than shaker lambs.

Infection in late pregnancy
Infection of the fetus after 80 days of gestation is likely to be controlled or eliminated by a fetal immunological response. Such lambs are born without clinical disease and are virus-negative but have precoelastin-circulating antibody.

**Goats**
In goats, fetal death is the major outcome of infection of the pregnant doe with both BDV and BVDV, and infections prior to 60 days’ gestation almost invariably result in reproductive failure. Persistently infected shaker kids and clinically normal kids are born with infections around 60 days’ gestation but are a less common manifestation of the disease than occurs in sheep. The caprine fetus develops immune competence against pestiviruses between 80 and 100 days’ gestation.

**Enteric disease**
Experimental inoculation of a homologous strain of the BDV into persistently infected, but clinically recovered lambs results in a severe clinical syndrome characterized by persistent diarrhea and respiratory distress associated with an inflammatory lymphoproliferative response in the central nervous system, intestines, lungs, heart, and kidney. A similar syndrome is seen at weaning in some persistently infected sheep that survive early life. This syndrome resembles certain aspects of mucosal disease in cattle, in which it is postulated that superinfection of persistently viremic immunotolerant cattle with a homologous strain of BVDV results in fatal mucus disease. In such animals a specific and dynamic equilibrium exists between an attenuated form of the virus and the immunotolerant host. Disturbance of this equilibrium either by injection of the homologous strain of BDV, or some other factor, results in fatal disease.

**CLINICAL FINDINGS**
The most obvious and characteristic features of border disease are evident at birth and relate to conformation and growth, fleece type, and neurological dysfunction.

**Conformation**
Affected lambs may have a lower birth weight than uninfected lambs, a decreased crown–rump length, and a shorter tibia/radius length so that they have a boxy appearance. The head has a shortened longitudinal axis and the cranium may be slightly domed (goat lambs).

**Fleece**
The fleece, when dry, appears hairy and rough due to long hair rising above the fleece to form a halo, especially over the nape, back, flanks and rump. This feature is most evident in medium- and fine-wool breeds and is not observed in the coarse kempy-fleeced breeds, such as the Scottish Blackface. The halo kemp fibers are shed with time and are more evident in the first 3 weeks of life. Some lambs have abnormal pigmentation occurring as patches of pigmented fleece or hair, or a totally pigmented fleece. This can occur in white-faced sheep.

**Neurological dysfunction**
Neurological dysfunction is manifest, with rhythmic tremors of the muscles of the pelvis and upper parts of the hindlimbs, or of the whole body, resulting in a characteristic jerking movement, and of the head and neck with rhythmic bobbing of the head (shaker lambs). In some less severe cases, only fine tremors of the ears and tail are evident. Tremors are most apparent during movement, and are absent while the lamb is sleeping. The tremors usually decline in severity as the lamb matures and may seem to disappear unless the animal is stressed. More severely affected lambs have difficulty in rising, and if able to stand with assistance exhibit an erratic gait especially of the hindquarters. Paralysis does not occur. Affected lambs are often unable to nurse the ewe because they cannot hold onto the teat. Affected lambs appear languid and lie around listlessly. They do not suck as they should and bloat continuously, and the ewes’ udders become engorged with milk.

**Behavioral and visual defects** with circling, head-pressing, nystagmus, and gross incoordination are seen in lambs with the type of infection producing hydranencephaly and cerebellar dysplasia. These lambs are of lighter birth weight but have normal birthcoats.

**Growth rate**
Growth rate is reduced, affected lambs are unthrifty, and the majority will die before or at weaning time from parasitism, pneumonia, a mucosal disease-like syndrome, or nephritis. With good nursing care they can be reared but deaths may occur at any age. Puberty may be delayed and, in males, the testes are flabby and may not develop normally.

**Reproductive performance**
Impaired reproductive performance of the flock occurs from low fertility, abortion, and poor viability of lambs. Abortions usually are not noticed until lambing when it is evidenced by an unexpected increase in barren ewes. In goats, where there is often closer observation, the aborted fetuses may be reasonably well developed, small and underdeveloped, or autolyzed and unrecognizable as a fetus in expelled fetal fluid.
CLINICAL PATHOLOGY
There are no consistent changes in hematologic or blood chemistry. Persistently infected lambs have changes in lymphocyte subpopulations, with a reduction in T-lymphocytes and an altered CD8:CD4 ratio. 6
Virus can be detected by virus isolation, by antigen ELISAs, by PCR techniques and antibody by antibody ELISAs, or by serum neutralization tests. 5,25 A combination of serology and virus isolation can aid in the diagnosis of border disease.

Detection of persistently infected sheep
For diagnosis of border disease in newborn lambs, precolostral blood samples should be taken from both clinically normal and affected lambs. Persistently infected sheep are seronegative and BDV can be isolated from leukocytes in the blood buffy coat. Lambs infected late in gestation will be seropositive but virus-negative. Persistently infected lambs that have received colostrum from their dam will be seropositive until they lose the maternal passive immunity.

Persistently infected adolescent and adult sheep in a flock can be identified by the detection of virus in blood; however, this is expensive in large flocks and an alternative is test all sheep for antibody and then culture the buffy coat of seronegative sheep. Antigenic differences between laboratory strains and field virus can result in false-negative serologies and serological studies are best done with the homologous virus. 6,26

Abortion
Serological tests are of limited value as an aid to the diagnosis of abortion associated with BDV infection. The infection of the ewe that results in abortion occurs several weeks before clinical disease is apparent, and unless prospective samples can be taken there is little chance of a rise in anti-body titers in paired samples. Seropositivity in ewes indicates that the flock has been exposed to pestivirus but does not incriminate it in a disease process. Seronegativity indicates that BDV is not the cause of the abortion, with the exception that aborting ewes, who themselves are persistently infected, will have no antibody titer.

NECROPSY FINDINGS
Gross findings may be normal, or may include an abnormal wool coat and a reduction in the size of the brain and spinal cord. Arthrogryposis, hydranencephaly, porencephaly, and cerebellar dysplasia may also be present. Histologically, there is a deficiency of stainable central myelin, with neurochemical and histochemical evidence of demyelination or myelin dysmorphogenesis. In most sheep the myelin defect resolves substantially during the first few months of life. The brain, which has been very small, returns to normal weight, and chemical composition and degree of myelination. The histological lesions of the skin consist of primary follicle enlargement, increased primary fiber size, and an increased number of modulated primary fibers.
Virus can be demonstrated by immunofluorescent staining of cryostat sections of tissues from affected lambs or by immunohistochemical staining of formalin-fixed material. Preferred tissues for such tests include brain, thyroid gland, and skin. Virus titers reach high levels in the placenta, so caruncles or cotyledons should be cultured for virus. Isolates are non-cytopathic and the presence of viral antigens must be demonstrated by direct or indirect immunofluorescence or immune peroxidase techniques.
Owing to the closely related character of this pestivirus and BVDV, diagnostic tests to confirm infection parallel those for BVDV. Fetal serology can be useful to confirm exposure in abortions and stillbirths. PCR and ELISA techniques may be substituted for virus isolation if available.

Samples for confirmation of diagnosis
- Histology – formalin-fixed skin, spinal cord, one-half of midsagittally sectioned brain, skin, thyroid, distal ileum, colon, cecum, thymus, spleen, liver, heart, kidney (LM, IHC)
- Serology – heart blood serum/thoracic fluid (VN)
- Virology – placenta/caruncle, thymus, lymph node, spleen, thyroid, brain, ileum (ISO, FAT, ELISA, PCR).

TREATMENT
There is no specific treatment. With care and nursing, many affected lambs will survive the immediate neonatal period but they grow poorly, are very susceptible to intercurrent disease during the growing period, and it is generally not economic to attempt to raise these lambs.

CONTROL
The principles are to attempt to engender a flock immunity and to avoid exposing sheep to infection in early pregnancy. Persistently infected sheep are a continuous source of infection and those that survive to breeding age can perpetuate the disease. They should be identified and culled.

The problem is with their identification, as some persistently infected lambs show no clinical or phenotypic abnormality. Lambs that are clinically affected at birth should be permanently identified since the tremor and fleece abnormality disappear at 1–2 months of age and the lambs may no longer be recognizable as infected. Persistently infected animals can be identified by serological screening of the ewe lambs intended for replacement stock at 6 months of age (after maternal passive immunity has waned), followed by virus isolation in seronegative animals, but this is expensive and only practical in small flocks. An alternative is to keep no replacement ewes from an affected lamb crop.

Persistently infected sheep can be run with the flock when it is not pregnant, particularly with the replacement ewes, in an attempt to produce infection and immunity prior to pregnancy. They should be removed prior to breeding. While this can result in 'natural vaccination' the rates of infection and seroconversion in replacement females can be low. 7 In theory, cattle BVDV vaccines could be used to produce immunity but their efficacy would depend upon a significant relatedness to the BDV under consideration.

In most flocks a serious outbreak of the disease is followed by minor disease in subsequent years, the flock developing immunity in the initial outbreak. In flocks that are free of infection, replacement ewes and rams should be screened for infection prior to purchase, or quarantined after arrival on the farm. Newly introduced sheep should be kept separate from the main flock until after lambing. Ideally, cattle should not be pastured or housed with pregnant sheep.

### Differential diagnosis list:

- Ulcerative dermatosis
- Proliferative dermatitis (strawberry foot rot)
- Blue tongue
- Foot and mouth disease
- Sheep pox

**Treatment**

Nothing specific; general care of lesions.

**Control**

Isolation of affected animals.

**Vaccination**

Methods of transmission

Scabs that fall off from healing lesions contain virus and remain highly infective for long periods in dry conditions, but survival of the disease in a flock may be the result of chronic lesions that exist for long periods on individual animals. Infection can be from environmental persistence of the virus or from infected sheep. Spread in a flock is very rapid and occurs by contact with other affected animals or by contact with contaminated inanimate objects, such as feed troughs, ear-tagging pliers. An outbreak of lesions on the tails is recorded in association with the use of docking instruments.

It has been assumed that natural infections on pasture are the result of invasion of the virus after skin damage induced by prickly plants or stubble; application of a viral suspension to scarified skin is the established method of inducing orf. However, an outbreak has occurred in a large group of lambs collected from several farms and transported in a vehicle over a period of 23 hours. There was no evidence of injury to their mouths.

### Experimental reproduction

The disease is readily reproduced by introduction of virus onto scarified areas of skin. Immunity to re-infection is relatively solid at the site of initial infection but shorter duration lesions can be reproduced by re-challenge of these sheep at other sites.

### Risk factors

The primary risk factors are the presence of the virus and the immune status of the sheep.

A simulated shipping exercise has examined these risks. Initially, the prevalence of scabby mouth on participating sheep farms was determined. The proportion of farms with evidence of the disease in weaner sheep was 23.6%, and on those farms with the disease the overall prevalence was 6.1%. Sheep from different farms are mixed, held at high stocking densities for approximately 3 weeks, and offered pelleted feed that can abrade the lips and mouth to promote development of the lesions. The major risk factor for the prevalence of the disease in sheep arriving in a feedlot after transportation from the farm was immunity to the disease. The arrival and mixing in the feedlot was also important for
transmission of the infection to occur. Sheep vaccinated on the farm before road transportation to the feedlot had a lower prevalence at the end of the simulated shipping exercise. Inter-current infections may exacerbate the occurrence disease on rare occasions. The disease has spread from clinically normal ewes to susceptible 2-4 years of age which were persistently infected with border disease virus and lambs experimentally infected with *Ehrlichia phagocytophilia* and subsequently challenged with orf virus developed more severe lesions with a longer course than those in control lambs. Economic importance 
The disease produces a minor set back except when it affects young sucking lambs with associated lesions on the teats and udders of their ewes. Loss from lamb mortality and secondary mastitis in these circumstances can be significant.

The disease assumed economic importance for Australia when shipments of sheep exported from Australia in 1989-1990 were rejected at some ports in the Middle East because of the disease and this problem continues. Litigation is a concern when zoonotic infections occur at petting zoos or fairs. Zoonotic implications 
Orf virus is readily transmitted to humans. In the agricultural environment typical lesions occur at the site of infection, usually an abrasion infected while handling diseased sheep for shearing, crutching or drenching or by accidental means when vaccinating. Lesions progress from macular to papular stages, are usually single and localized on the hands, arm or face. The lesions are self limiting and heal without scarification after 6 to 7 weeks. They are pruritic and respond poorly to local treatment. Orf is also a zoonotic consideration in 'petting zoos' and fairs where children allow lambs to suck their fingers or otherwise become infected from handling sheep exhibits. Historically, orf has been a risk for industrial workers handling raw wool. PATHOGENESIS 
Damage to the skin is essential for the establishment of orf infection and the development of typical lesions. Following viral challenge of mildly abraded skin, the virus does not establish in the damaged epidermis, but replicates in the cells of an underlying replacement epidermal layer derived from the walls of the wool follicles. Following scarification of ovine skin and topical application of the orf virus, antigen cannot be detected in the skin during the period when the epidermis is being renewed. Virus can first be detected in the center of the newly differentiated epidermis immediately below the stratum corneum, 72 hours after infection. The location of the virus during the eclipse stage is unknown. The infection spreads laterally and uniformly from the new epidermis, initially in the outer stratum spinosum and subsequently throughout the entire depth of the epidermis. The skin reaction consists of a cellular response with necrosis and sloughing of the affected epidermis and underlying stratum papillare of the dermis. The cutaneous response to infection includes a delayed-type hypersensitivity reaction and an influx of inflammatory cells involving neutrophils, basophils, and possibly mast cells. Class II dendritic cells are also involved and appear to form the basis of a highly integrated local dermal defense mechanism. The lesions evolve through the stages of macule, papule, vesicle, pustule, scab formation, and resolution. The pustules develop within a few days, and rupture resulting in ulcers and subsequently a thick overlying crust or scab forms which is shed within 3-4 weeks leaving no scar. Immunity is solid but will last only about 8 months. While there is an antibody immune response to the virus recovery is the result of cell-mediated immune mechanisms. Experimentally, a secondary infection, following recovery from a primary infection, is milder and accelerated. During the secondary challenge, pustules and scabs develop earlier, the lesions resolve more rapidly, and no vesicular stage may occur.

CLINICAL FINDINGS Sheep 
Lesions develop initially as papules and then pustules, stages which are not usually initially observed, and progress to raised moderately proliferative area of granulation, and inflammation covered with a thick, tenacious scab. Time progression from the initial lesions to the formation of scabs is approximately 6 to 7 days. New lesions will develop during the first 10 days of infection. The first lesions develop at the oral mucocutaneous junction, usually at the oral commissures and are accompanied by swelling of the lips. From here they spread on to the muzzle and nostrils, the surrounding haired skin and, to a lesser extent, on to the buccal mucosa. They may appear as discrete, thick scabs 0.5 cm in diameter, or coalesce and be packed close together as a continuous plaque fissuring occurs and the scabs are sore to the touch. They crumble easily but are difficult to remove from the underlying granulation. Affected lambs suffer a severe setback because of restricted sucking and grazing. In benign cases the scabs dry and fall off, and recovery is complete in about 3 weeks. Affected lambs sucking ewes may cause spread of the disease to the udder where a similar lesion progression is seen. Lesions on the teats predispose to mastitis and secondary infection of the skin lesions by bacteria or fly larvae occurs in some cases. In rams, lesions on the scrotum may be accompanied by fluid accumulation in the scrotal sac and associated temporary infertility. A high incidence of infection can also occur where the dominant lesions are on the feet, occurring around the coronary band, the dew claws and on the volar areas of the intervening skin.

Rarest systemic invasion occurs and lesions appear on the coronets and ears, around the anus and vulva or prepuce, and on the nasal and buccal mucosas. There is a severe systemic reaction, and extension down the alimentary tract may lead to a severe gastroenteritis, and extension down the trachea may be followed by bronchopneumonia. Lesions may also occur in the mouth involving the tongue, gums, dental pad or a combination of those sites. These are more commonly seen in outbreaks affecting lambs less than 2 months of age. In the mucosa of the mouth these lesions do not scab but are papular erosive and surrounded by an elevated zone of hyperemia. Extensive painful and proliferative lesions occur on the gingival margins of the incisor teeth.

In some outbreaks the lesions on the skin are highly proliferative and present as raw raised granulating lesions without an overlying scab. This manifestation appears more common in Suffolk sheep and lesions are present on the lips, bridge of the nose and around the eyes. Cases of this proliferative form involving the feet are also recorded. A malignant form of the disease has also been observed in sheep. It begins with an acute episode manifested by oral vesicles, and extension of these lesions down the gastrointestinal tract, followed later by granulomatous lesions and shedding of hooves.

An atypical case of the disease in sheep after extensive cutaneous thermal injury has been described. The virus was present in proliferative verrucous tissue lesions at the periphery of the original thermal injury. The lesions consisted of tightly packed 0.5 mm-diameter papillary projections.

Goats 
An unusual case of contagious ecthyma in a group of female goats has been described. Multifocal lesions occurred over the head, neck, thorax, and flanks of...
The lesions developed approximately 2 weeks after the animals returned from a local summer show at which the does were housed for 3 days in pens previously occupied by sheep. The lesions began as plaques, followed by epidermal proliferation and severe encrustation. Affected areas were discrete and approximately 2–7 cm in diameter. There were no lesions of the muzzle, lips, udder or teats. Recovery occurred uneventfully within 3–6 weeks without treatment. The skin crusts gradually dried and fell off, leaving areas of alopecia and depigmented skin. Regrowth of hair followed.

Persistent orf is recorded in a proportion of Boer goats following an outbreak. The disease in the majority of the animals in the herd was classical and ran a clinical course of 3–4 weeks but in 2% of animals it persisted for several months and lesions disseminated over the body. There were no particular distinguishing differences of the virus genome to those of other orf viruses and the persistence was possibly a result of individual host susceptibility factors.

**CLINICAL PATHOLOGY**

Electron microscopic identification of the virus is quick and generally reliable with multiple samples from an affected herd or flock. Virus can also be detected by PCR and restriction enzyme analysis of viral DNA and gene sequencing. Recovered animals have a high level of neutralizing antibodies in their serum and this is detectable by a gel diffusion test and other serological tests but has little clinical value.

**NECROPSY FINDINGS**

In malignant cases there are irregularly-shaped lesions, with a hyperemic border in the oral cavity and the upper respiratory tract, with rare involvement of the mucosa of the esophagus, abomasum, and small intestine. Typical lesions are actually proliferative, with subsequent loss of centrally located cells creating an ulcer-like appearance. Microscopically, the hyperplastic epithelium contains inclusion bodies.

**Samples for confirmation of diagnosis**

- **Histology** – formalin-fixed lesions (LM)
- **Virology** – vesicle fluid, scraping from lesion (EM).

**DIFFERENTIAL DIAGNOSIS**

| In most outbreaks of eczema, the cases are sufficiently mild to cause no real concern about losses or about diagnosis. | Dramatic outbreaks of a very severe form of the disease may occur, however, and are likely to be confused with bluetongue. Very severe cases are also commonly seen in housed experimental sheep especially colostrum-free lambs. Ulcerative dermatosis is sufficiently similar to cause confusion in diagnosis, but this disease has not been reported in many years. **Myotic dermatitis** usually occurs on woolled skin but lesions can occur on the lips and feet (strawberry foot rot), have a thick dry adventitious-like scab and are easily differentiated by laboratory culture. **Facial eczema** is distinguished by diffuse dermatitis and severe edema and damage to the ears. **Papillomatosis** (warts) need also to be considered in the differential diagnosis for the proliferative manifestations of contagious ecthyma, although warts are extremely uncommon in sheep. Bluetongue is always accompanied by a high mortality rate, a severe systemic reaction, and lesions occur on the muzzle, the coronets, and extensively on the buccal mucosa. It is more common in adults than sucking lambs. Because it is transmitted by insect vectors, the morbidity rate is usually much less than the 90% commonly seen in contagious ecthyma. Sheeppox may present a rather similar clinical picture, but the lesions are typical, there is a severe systemic reaction and heavy mortality rate. **Foot and mouth disease**. The classic developed lesions of orf are easily differentiated from foot and mouth disease but the papular and vesicular stages seen early in the course of orf, particularly lesions in the mouth, can be difficult to differentiate especially when a prompt on-farm differentiation is required. The raised firm papular erosive nature of the lesion with the surrounding zone of hyperemia is a crucial differentiating feature in the field.

**TREATMENT**

There is no specific treatment. Removal of the scabs and the application of ointments or astrigent lotions are practiced but delay healing in most cases. The provision of soft, palatable food is recommended. The combined use of diathermy debridement and cryosurgery is claimed to be effective for the proliferative intraoral lesions in young lambs.

**CONTROL**

In the early stages of an outbreak, the affected animals should be isolated and the remainder vaccinated. Vaccination is of little value when a large number of animals are already affected. Persistence of the disease in a pastured flock from year to year is common and in such circumstances the lambs should be vaccinated at 6–8 weeks of age. Vaccination when a few days old evokes a protective response, but prelambing vaccination of the ewe does not and is not recommended. Vaccination of housed lambs should be timed to avoid the usual occurrence of the disease that has been observed in previous years.

The vaccine is prepared from a suspension of scabs in glycerol saline and is painted onto a small area of scabbed skin inside the thigh, or by pricking the ear with a needle dipped in the vaccine. Vaccination is completely effective for at least 2 years, but the lambs should be inspected 1 week after vaccination to insure that local reactions have resulted. Absence of a local reaction signifies lack of viability of the vaccine or the existence of a prior immunity. The immunity is not sold until 3 weeks after vaccination. A small proportion of vaccinated lambs may develop mild lesions about the mouth because of nibbling at the vaccination site. The efficiency of this vaccine is greater than that of the standard commercial vaccine containing live attenuated virus. As a further protective measure, removal of abrasive material from the environment is recommended but is not usually practicable. For live sheep being transported from Australia to the Middle East, it is suggested animals be vaccinated well in advance of shipment to allow immunity to develop, which is probably at least 3 weeks.

Because the vaccines are live virus vaccines, and shed scabs are contaminated, routine vaccination against orf in flocks that have not experienced the disease is not recommended.

Outbreaks have occurred from vaccine virus.

**CONTROL**

In the early stages of an outbreak, the affected animals should be isolated and the remainder vaccinated. Vaccination is of little value when a large number of animals are already affected. Persistence of the disease in a pastured flock from year to year is common and in such circumstances the lambs should be vaccinated at 6–8 weeks of age. Vaccination when a few days old evokes a protective response, but prelambing vaccination of the ewe does not and is not recommended. Vaccination of housed lambs should be timed to avoid the usual occurrence of the disease that has been observed in previous years.

The vaccine is prepared from a suspension of scabs in glycerol saline and is painted onto a small area of scabbed skin inside the thigh, or by pricking the ear with a needle dipped in the vaccine. Vaccination is completely effective for at least 2 years, but the lambs should be inspected 1 week after vaccination to insure that local reactions have resulted. Absence of a local reaction signifies lack of viability of the vaccine or the existence of a prior immunity. The immunity is not sold until 3 weeks after vaccination. A small proportion of vaccinated lambs may develop mild lesions about the mouth because of nibbling at the vaccination site. The efficiency of this vaccine is greater than that of the standard commercial vaccine containing live attenuated virus. As a further protective measure, removal of abrasive material from the environment is recommended but is not usually practicable. For live sheep being transported from Australia to the Middle East, it is suggested animals be vaccinated well in advance of shipment to allow immunity to develop, which is probably at least 3 weeks.

Because the vaccines are live virus vaccines, and shed scabs are contaminated, routine vaccination against orf in flocks that have not experienced the disease is not recommended.

Outbreaks have occurred from vaccine virus.
PAPILLOMATOSIS (WARTS)

**ETIOLOGY**
Cutaneous warts in cattle, horses, sheep and goats are benign tumors induced by host specific papillomaviruses. These infect epithelial cells causing hyperproliferative lesions that are benign, self-limiting and, in most cases, spontaneously regress. Differentiation of types is based on the histological features of the lesion and DNA identification by hybridization or the papilloma virus PCR. There has been little research on the papillomavirus of horses or small ruminants, but in cattle six types have been identified: bovine papilloma virus (BPV-1), BPV-2 and BPV-5, which cause fibropapillomas; and BPV-3, BPV-4 and BPV-6, which cause true epithelial papillomas.

Cattle types show some site predilection or site specificity. Their detailed roles are:
- **BPV-1** - frond fibropapillomas of teat skin and penile fibropapilloma
- **BPV-2** - cauliflower-like fibropapillomas of the anogenital and ventral abdominal skin
- **BPV-3** - associated with bladder cancer in cattle in association with the ingestion of bracken fern (*Pteridium spp.*)
- **BPV-4** - associated with the esophagus, esophageal groove, forestomachs and small intestine; this is capable of becoming malignant, particularly in animals fed bracken fern.
- **BPV-5** - rice grain fibropapilloma on the udder.
- **BPV-6** - frond epithelial papillomas of the bovine udder and teats.

Although a single BPV type is detected in an individual papilloma, a single animal may have papillomas at different sites associated with different BPV types.

Other papilloma of cattle that have regional distribution and may have separate antigenic identity are:
- Oral papillomas, mostly in adult cattle and apparently reaching a high incidence, up to 16% in some areas; these are probably BPV-4.
- Papilloma of the larynx in steers.
- Papillomavirus has been observed in squamous cell carcinoma of bovine eyes.

Other skin lesions in which papillomavirus plays an etiological role are:
- Equine sarcoïd which associated with BPV-1 and BPV-2.
- Ear cancer of sheep.
- Papillomas in horses may be associated with a distinct equine papillomavirus.

**EPIDEMIOLOGY**

**Occurrence**
Papillomatosis has an international occurrence in all animal species.

**Origin of infection and transmission**
The method of spread is by direct contact with infected animals, infection gaining entry through cutaneous abrasions. Virus can also persist on inanimate objects which cause true epithelial papillomas on the larynx of feedlot steers is ascribed to implantation of the virus in contact ulcers, which are also entry sites for *Fusobacterium nodosus* (a cause of calf diphtheria), so that the two diseases may occur in the one animal. An outbreak of peri-orbital papillomatosis in cattle is recorded in association with a heavy periorbital infestation with *Haematopinus quadripertusus*.

**Animal risk factors**
All species may be affected but the disease is commonest in cattle and horses. With cattle, usually several animals in an age group are affected. Outbreaks have been recorded in sheep and goats, but the disease is uncommon in sheep. It is also uncommon in pigs, usually affecting the genitalia. Amongst wildlife, it occurs in white-tailed deer (*Odocoileus virginianus*) and mule deer (*O. hemionus*).

**Age**
Cutaneous papillomas of the head and neck occur predominantly in young animals, the lack of susceptibility of adults to natural infection being ascribed to immunity acquired by apparent or inapparent infection when young. The occurrence of cutaneous warts and their severity can be influenced by factors that induce immunosuppression, and latent infection has converted to clinical disease with the administration of immunosuppressive agents. Congenital infection is recorded in the foal and calf, but is rare.

Alimentary papillomas associated with BPV-4 in cattle, rice grain teat papillomas associated with BPV-5 in cattle, and papillomas on the mammary glands of goats occur, or persist, at all production ages.

**Experimental production**
The supernatant from a suspension of wart tissue, injected ID, or applied to skin scarifications, is an effective means of experimental production of the disease. Lesions are restricted to the site of inoculation. Cutaneous and oral papillomas have been transmitted in cattle, and cutaneous papilloma transmitted in sheep and horses. The incubation period after experimental inoculation in cattle is 3–8 weeks but is usually somewhat longer after natural exposure.

**Economic importance**
Cutaneous warts are quite common in young cattle, especially when they are housed, but ordinarily they cause little harm and regress spontaneously. In purebred animals they may interfere with sales and shows because of their unsightly appearance. Animals with extensive lesions may lose condition, and secondary bacterial invasion of traumatic lesions may occur.
...matized warts may cause concern. Warts on the teats of dairy cows often cause interference with milking. In horses, the lesions are usually small and cause little inconvenience, but they are esthetically unattractive. In all species, the development of warts on the genitalia requires immediate treatment.

**PATHOGENESIS**

The virus infects the basal keratinocytes, replicating its genome in the differentiating spinous and granular layers causing the excessive growth that is characteristic of wart formation. Expression of the late structural proteins of the virus is limited to the differentiated cells of the squamous layer where the new virus particles are encapsulated and shed into the environment as the cells die. The tumor contains epithelial and connective tissues and can be a papilloma or a fibropapilloma, depending on the relative proportions of epithelial and connective tissue present; papillomas contain little connective tissue, and fibropapillomas are mostly fibrous tissue, with very little epithelial tissue. Papillomas are the result of basal cell hyperplasia without viral antigen production. Fibropapillomas are uncommon in horses, but are the common lesion in cattle, sheep, and wild ruminants. Latent infection in the skin and lymphocytes has been demonstrated in cattle.

**CLINICAL FINDINGS**

Warts are solid outgrowths of epidermis and may be sessile or pedunculated.

**Cattle**

In cattle, warts occur on almost any part of the body, but when a number of animals in a group is affected it is common to find them all affected in the same part of the body. The most common papillomas occur in the skin of cattle under 2 years of age, most commonly on the head, especially around the eyes, and on the neck and shoulders, but may spread to other parts of the body. They vary in size from 1 cm upwards and their dry, horny, cauliflower-like appearance is characteristic. In most animals they regress spontaneously, but the warts may persist for 5–6 months, and in some cases for as long as 18 months, with serious loss of body condition.

Warts on the teats manifest with different forms depending on the papilloma virus type and may show an increasing frequency with age. The frond form has frilliform projections on them and appear to have been drawn out into an elongated shape of about 1 cm in length by milking machine action. If sharp traction is used they can often be pulled out by the roots.

Other forms are a flat, round type which is usually multiple, always sessile and up to 2 cm in diameter. The third form has an elongated structure appearing like a rice grain. Teat warts may regress during the dry period and recur with the next lactation.

**Perianal warts** are esthetically unattractive, but do not appear to reduce activity or productivity. Genital warts on the vulva and penis make mating impracticable because the lesions are of large size, are friable, and bleed easily. They commonly become infected and flyblown. They occur on the shaft or on the glans of the penis in young bulls, may be single or multiple, are pedunculated and frequently regress spontaneously.

**Alimentary tract** warts are rarely observed clinically in farm animals in most countries, but are recorded in abattoir cattle at a high incidence in some localities and have been reproduced experimentally. Papillomas occur on the lateral and dorsal aspects of the tongue, the soft palate, oropharynx, esophagus, esophageal groove, and rumen. Papillomas occurring in the esophageal groove and in the reticulum are a cause of chronic ruminal tympany.

Less common manifestations of papillomatosis in cattle include lesions in the urinary bladder, which cause no clinical signs but may predispose to enzootic hematuria. BFV-4 papillomas in the upper alimentary tract of cattle being fed bracken fern are the focus for transformation to squamous cell carcinomas. Cattle fed bracken fern are immunosuppressed, which promotes the persistence and spread of the papilloma virus, and mutagens in bracken fern cause neoplastic transformation of papilloma cells.

**Goats**

Papillomas most commonly occur on the face and ears but may occur on the skin generally, especially on unpigmented skin. Most completely regress, others regress and recur, and occasional lesions progress to carcinomas. Papillomas that occur on the teats are persistent and may spread through the herd.

**Horses**

Warts are confined to the lower face, the muzzle, nose and lips, and are usually sessile and quite small, rarely exceeding 1 cm in diameter. They may also occur on the penis and vulva, in the mouth, and on the conjunctiva. All ages can be affected. Spontaneous recovery is usual, but the warts may persist for 5–6 months.

**TREATMENT**

Warts can be removed by surgery or cryosurgery. Crushing of a proportion of small warts, or the surgical removal of a few warts, has been advocated as a method of hastening regression but the tendency for spontaneous recovery makes assessment of the results of these treatments very difficult. Partial resection of a wart(s) in a horse does not always promote resolution of the residue. Surgical removal can be followed by vaccination with an autogenous vaccine. Surgical intervention, and even vaccination, in the early stages of wart development may increase the size of residual warts and prolong the course of the disease.

**Vaccination**

For cattle, autogenous vaccines prepared from wart tissues of the affected animal are effective in many cases. Commercially available vaccines are available for cattle but may be less efficacious; an autogenous vaccine prepared for a specific problem has the advantage of including the local virus types. The vaccine is prepared from...
homogenized wart tissue that is filtered and inactivated with formalin. Because of the different BPV types, care is required in the selection of the tissues. In general terms they can be selected on tumor type, location, and histological composition. The alternative is to use many types of tissue in the vaccine. Animal to animal variation in regression following vaccination of a group of calves with a vaccine prepared from a single calf in the group has been attributed to more than one BPV type producing disease in the group. The stage of development is also important, and virus is present in much greater concentration in the epithelial tissue of older warts than young ones. The vaccine can be administered SC, but better results are claimed for ID injection. Dosing regimes vary, but 2–4 injections 1–2 weeks apart are commonly recommended. Recovery in 3–6 weeks is recorded in 80–85% of cases where the warts are on the body surface or penis of cattle, but in only 33% when the warts are on the teats. The response of low, flat, sessile warts to vaccination is poor. Other treatments no longer commonly used include the injection into the wart of proprietary preparations containing antimony and bismuth or the intralesional injection of bacille Calmette–Guerin (BCG).

CONTROL
Specific control procedures are usually not instituted or warranted because of the unpredictable nature of the disease and its minor economic importance.

Vaccination has been shown experimentally to be an effective prevention and gives complete protection in cattle against stiff experimental challenge. The vaccine must contain all serotypes of the papillomavirus because they are very type-specific. Avoidance of close contact between infected and uninfected animals should be encouraged, and the use of communal equipment between affected and unaffected animals should be avoided.

REVIEW LITERATURE

REFERENCES

ETIOLOGY
The cause of sarcoïd in horses, mules, and donkeys is almost certainly bovine papillomavirus (BPV) types 1 or 2. It is assumed that this is a null-producing infection in which viral DNA exists episomally.3

However, given the demonstration of genetic susceptibility to sarcoïd, the cause is almost certainly multifactorial, with virus infection being an inciting event in susceptible animals.3 There does not appear to be a role for mutation in the tumor suppressor gene, p53, in the development of sarcoïd in horses.8

EPIDEMOLOGY
Occurrence and prevalence
Equine sarcoïd is the commonest neoplasm in horses, representing about 20% of all equine tumors diagnosed at necropsy. Horses, donkeys, and mules are affected. Sarcoïd tumors occur in 0.7% of Swiss warmblood, and 0.4% of Freiberger horses in Switzerland.1 Of the horse breeds, Appaloosa, Arabian, and Quarter horses are at more risk than are Standardbreds or Thoroughbreds.9

Methods of transmission
Transmission can be by infection of wounds and castration is believed a risk factor, with flies as possible vectors.10 Close contact may facilitate transmission.2 BPV DNA has been detected in face flies (Musca autumnalis) associated with horses with sarcoïds.3

Experimental reproduction
The disease has been transmitted with sarcoïd tissue and cell free supernatant from minced sarcoïd tumors. The disease has also been reproduced with bovine papillomavirus although the experimentally produced tumors subsequently regressed which seldom occurs with natural sarcoïd.3

Animal risk factors
There is a genetic-based susceptibility to the disease,7 and the predisposition of horses to sarcoïd is associated with the type of major histocompatibility complex.11 Approximately 40% of the susceptibility to the disease in Swedish Halbreds is attributable to an autosomal, dominant equine leukocyte antigen (ELA)-linked gene.2 The prevalence in quarter horses is greater than that in thoroughbreds, and in both is higher than that in standardbreds.5 Sarcoïd are very rare in horses less than 1 year of age, and the prevalence is highest in horses 1 to 6 years-of-age. Young males appear more at risk, possibly related to castration.10

Environmental risk factors
Lesions commonly occur on traumatized areas.

PATHOGENESIS
Sarcoïds are localized proliferations of epidermal and dermal tissue which may remain small and dormant for many years and then undergo a stage of rapid cancer-like growth. The lesions show moderate malignancy but do not metastasize to other sites, although there may be multiple cutaneous lesions. The virus infects fibroblasts and the infection is non-productive. It is believed that virus capsids of BPV are not found in equine sarcoïds because papillomavirus are usually host specific and the expression of virus capsids of the bovine papillomavirus...
requires the cellular environment of keratinocytes of the host species. Sarcoids do not regress, in contrast to the majority of papillomavirus infections, probably because expression of BPV in equine cells elicits immune evasion mechanisms.

### CLINICAL FINDINGS
Sarcoids occur as single, or more commonly, multiple lesions or clusters in the skin. The lesions occur most commonly on the lower limbs but also on the lips, eyelids, eye, penile sheath, and around the base of the ears.

Several forms of sarcoid are described:

- **Verrucous (warty) sarcoid** is a dry, horny, cauliflower-like surface that is usually partially or completely hairless. It may be broad based (sessile) or pedunculated. Verrucous sarcoids occur most commonly on the face, body, groin and sheath area. It has a predilection
- **Fibroblastic sarcoid** has a similar appearance to that of proud flesh or excessive granulation tissue. It is often a firm, fibrous nodule in the dermis, although the surface may be ulcerated. It is found most commonly at sites of previous wounds and also the eyelid and limbs
- A combination of both of the forms described above
- **Occult sarcoid** is typically an area of slightly thickened skin that has a roughened surface. It is usually partially hairless. Interference with these slow-growing sarcoids, including attempts at treatment, should be avoided; as such interference can cause the tumor to proliferate. They occur most commonly around the mouth and eyes and on the neck.

### CLINICAL PATHOLOGY
Confirmation of the diagnosis requires a biopsy specimen for histologic examination. Because sarcoids are usually associated with excessive granulation tissue and pyogranulomatous debris, the preferred specimen is a transverse section of the excised tumor. If punch biopsies are to be collected, then care should be taken that they include a representative section of the tumor, and not just peripheral granulation tissue and edematous non-tumor material. Examination by a pathologist accustomed to examining equine skin sections is important, as the tumor has some features in common with papillomas and sarcomas and may be easily misdiagnosed.

PCR has been used to detect BPV DNA but the sensitivity is less than optimal.

### DIFFERENTIAL DIAGNOSIS
- Cutaneous habronemiasis
- Phymocytes
- Fibroma
- Granulation tissue
- Squamous cell carcinoma, especially of the penis and eyelid
- Other skin tumors, including melanoma by examination of a biopsy of the lesion
- Papillomatosis is a disease of young horses, and unlike sarcoid, commonly spontaneously regresses.

### TREATMENT
**Surgical excision** results in the return of the tumor in a significant proportion of animals within 6 months, often with over-proliferation. BPV DNA can be detected in normal skin immediately surrounding sarcoids and the recurrence reflects activation of latent BPV in normal tissue surrounding the tumor.

**Cryotherapy** is associated with a much lower recurrence rate but its use is limited by the anatomical location of the tumor. For instance, cryotherapy is not recommended for periocular lesions because of the risk of damaging nearby ocular tissues. The efficacy of cryotherapy may be enhanced by the use of thermocouples to monitor the temperature of the lesion to insure adequate freezing. At least two or three freeze–thaw cycles are necessary.

**Radiation therapy** using radon-222, gold-198, cobolt-60 or iridium-192 has been used and is indicated for recurrent or surgically inaccessible sarcoids such as periocular sarcoid. Radiation therapy is also useful for treating sarcoids of the body and legs. Local hyperthermia induced by a radiofrequency current of 2 MHz is also reported to be effective.

**Immunotherapy**, by injection of live organisms, killed bacilli, or cell wall extract of the bacillus of Calmette and Guerin (BCG) have been successful on occasion, but their efficacy depends on the size of the lesion, its anatomical location, and possibly its type. Immuno-therapy may work by inducing tumor-specific immunity. Side-effects include local reactions characterized by edema and systemic anaphylactoid reactions after the second or third injections if commercial, whole-cell vaccines are used. Vaccines composed of cell-wall fractions in oil are free of such reactions and have given good results in periocular lesions, but sarcoids of the axilla did not react favorably. Large sarcoids or cases with multiple lesions may also respond poorly. Immunotherapy using mycobacterial cell wall skeleton combined with trehalose dimycolate has resulted in total tumor regression.

### REFERENCES

### SUMMARY
Autogenous vaccines may result in the regression of existing sarcoids but have risk of inducing new tumors and are not recommended for routine therapy. A variety of chemical agents have been used for treatment but there are no controlled trials.

As yet, no single treatment modality is universally successful in the treatment of sarcoid. In a study in 92 horses comparing outcome, a successful outcome was obtained in 79% of horses treated with BCG vaccination, 82% of those treated with conventional excision and 71% of those treated using carbon dioxide laser.

### LUMPY SKIN DISEASE
(KNOPEVLSIEKTE, LSD)

**SYNOPSIS**
Lumpy skin disease virus, of the genus Capripoxirus

**ETIOLOGY**
Lumpy skin disease virus, of the genus Capripoxirus

**Epidemiology**
Endemic in sub-Saharan Africa and Middle East with recent incursion into Israel. Epizootics interspersed with periods of sporadic occurrence. Transmission by contact and arthropod vector

**Clinical findings**
Fever, nodular lesions on the skin and mucous membranes and lymphadenopathy. Proportion of cattle develop generalized infection with high mortality
Clinical pathology
Intracellular, eosinophilic inclusion bodies in biopsy material. Virus isolation. Fluorescent antibody and serum neutralization tests.

Necropsy findings
Nodules in skin, upper alimentary, respiratory tract.

Diagnostic confirmation
Biopsy and histology. Virus isolation.

Treatment
Supportive

Control
Vaccination

ETIOLOGY

Lumpy skin disease (LSD) is a severe, systemic disease of cattle associated with the Neethling poxvirus, a capripoxvirus. It has close antigenic relationship to sheeppox and goatpox viruses which are also in the same genus. There appears to be a difference in virulence between strains.

EPIDEMIOLOGY

Occurrence
The disease used to be confined to sub-Saharan Africa, but it is now enzootic in Egypt, and has occurred in Israel where it was eradicated by slaughter of infected and in-contact animals. Some field outbreaks are associated with severe and generalized infections and a high mortality, while with others there are few obviously affected animals and no deaths but in general outbreaks are more severe with the initial introduction of the infection to a region and then abate, probably associated with the development of widespread immunity. Morbidity rates reach 80% during epizootics, but are nearer 20% in enzootic areas. Morbidity rates of 31% are recorded in Egypt, and a morbidity of 10% in the recent incursion into Israel. In Kenya, the disease is characterized by a much lower mortality rate and the disease is much milder. Case fatality rates average 2%, but vary with the outbreak. Israel has experienced no direct mortality from the disease. There has been a resurgence of the disease in South Africa in the past decade probably due to higher rainfall and a decrease in the use of vaccination consequent to a previously low incidence.

Origin of infection and transmission
Cattle can be infected by drinking water, but ingestion and direct contact transmission are not common routes, even though the virus is present in nasal and lacrimal secretions, semen, and milk of infected animals. Most cases are believed to result from transmission by an arthropod vector. Historically, LSD virus has been isolated from Stomoxys calcitrans and Musca domestica and transmitted experimentally using S. calcitrans but other vectors are also suspect including Bioneza, Culicoides, Glossina and Musca spp. However, in a recent study, despite the detection of virus in mosquitoes (Anopheles stephens, Culex quinquefasciatus) the stable fly and a biting midge (Culicoides neotreulosis) after they had fed on cattle with lumpy skin disease, the infection did not transmit to susceptible cattle when these arthropods were allowed to re-feed on them.

Risk factors
Animal risk factors
All ages and types of cattle are susceptible to the causative virus, except animals recently recovered from an attack, in which case there is a solid immunity lasting for about 3 months. In outbreaks, very young calves, lactating and malnourished cattle develop more severe clinical disease.

British breeds, particularly Channel Island breeds, are much more susceptible than zebu types, both in numbers affected and the severity of the disease. Morbidity rates of 4-12% are recorded in water buffalo (Bubalis), but no further such cases are recorded.

Pathogen risk factors
Capripox viruses are generally resistant to drying, survive freezing and thawing. Resistance to heat is variable but most are inactivated at temperatures above 60°C.

Environmental risk factors
Outbreaks tend to follow waterways and extensive epizooties are associated with high rainfall and concomitant high levels of insect activity with a peak of disease in the late summer and early autumn.

Pathogen risk factors
Capripox viruses are generally resistant to drying, survive freezing and thawing. Resistance to heat is variable but most are inactivated at temperatures above 60°C.

Experimental production
Experimental transmission can be accomplished using ground-up nodular tissue and blood, or tissue culture virus. Disease is produced following intranasal, ID or IV challenge.

While lumpy skin disease is characterized by generalized nodular skin lesions, less than 50% of natural or experimental infections develop generalized skin nodules and the length of the viremic period does not correlate with the severity of the clinical disease.

Economic importance
The mortality rate is low, but the economic loss is high. In all cattle there is severe loss of milk production and the occurrence of secondary mastitis predisposed by the development of lesions on the teats. Loss also occurs from damage to hides, the loss of body condition during the course of the disease, and the loss of fertility in affected bulls. Cow may abort in the course of the disease. Lumpy skin disease is considered to be one of the high risk diseases for spread out of Africa to the outside world and a potential agent of agroterrorism.

PATHOGENESIS
In the generalized disease there is viremia accompanied by a febrile reaction, and localization in the skin occurs with development of inflammatory nodules. In the experimental disease, following ID inoculation, local lesions can develop at the site of challenge without viremia and generalized of the infection.

CLINICAL PATHOLOGY

Antigen detection. Diagnosis is most commonly made by electron microscopic
demonstration of typical capripox virions in full thickness skin biopsies or scabs coupled with the clinical findings of a generalized nodular skin disease with enlarged superficial lymph nodes. Biopsy of lesions reveals a granulomatous reaction in the dermis and hypodermis. In infection, much longer than detection an antigen will also react, like parapox virus. A recent study in experimentally infected indirect fluorescent antibody tests are commonly used. cattle found that virus in skin lesions could be detected by PCR for 90 days after vaccination. Serology. Virus neutralization the indirect fluorescent antibody tests are commonly used. AGID tests may give false-positive reactions due to cross-reactation with bovine papular stomatitis virus and pseudocowpox virus.

NECROPSY FINDINGS
The cutaneous lesions are described under clinical pathology. Similar lesions are present in the mouth, pharynx, trachea, skeletal muscle, bronchi and stomachs, and there may be accompanying pneumonia. The superficial lymph nodes are usually enlarged. Respiratory distress and death are often the result of respiratory obstruction by the necrotic ulcers and surrounding inflammation in the upper respiratory tract and/or concurrent aspiration pneumonia. Histologically, a widespread vasculitis reflects the viral tropism for endothelial cells. Intracytoplasmic viral inclusion bodies may be seen in a variety of cells types.

Samples for confirmation of diagnosis
- Histology – formalin-fixed lesions from skin, alimentary and respiratory tissue, lymph node (LM)
- Virology – lymph node, skin lesion (ISO).

DIFFERENTIAL DIAGNOSIS
The rapid spread of the disease and the sudden appearance of lumps in the skin after an initial fever make this disease quite unlike any other affliction of cattle.

Pseudo-lumpy skin disease (also known as Allerton virus infection and ‘general infection of cattle with bovine herpesvirus-2’), is associated with bovine herpesvirus-2, the agent of bovine mammaryitis. It occurs primarily in southern Africa, but very occasional cases are recorded in the United States, Australia, and the United Kingdom and is stated to occur more commonly in the southern United States than formally recognized. Multifocal lesions are distributed over the body, and are circular, up to 2 cm in diameter, with loss of hair and an intact central area and raised edges. Some lesions show a circular ring of necrosis around a central scab. The scabs fall off leaving discrete hairless lesions that may be depigmented. The disease runs a course of approximately 2 weeks and there is no mortality. Only the superficial layers of skin are involved. This is in contrast to the lesions of lumpy skin disease, which are often deep enough to expose underlying tissues. Herpesvirus can be isolated from the periphery of the lesions. Diagnosis can be made by PCR on full-thickness skin biopsy.

TREATMENT
No specific treatment is available, but prevention of secondary infection is essential. The use of antibiotics or sulfonamides is recommended.

CONTROL
Lumpy skin disease moves into new territory principally by means of the movement of infected cattle or possibly by wind-borne vectors. In the new territory further spread is accepted as being via an insect vector. Control of cattle movement from uninfected to infected territory is an important control measure. Further control can only be by vaccination.

Vaccination
A safe and effective vaccine has been produced by 60 passages of the virus through lamb kidney culture. It is administered to all animals over 6 months of age and is effective, but is associated with considerable local reaction that may persist over 1 month and may predispose fly strike. Local response to the vaccine is usually correlated with good antibody response. A freeze-dried, living attenuated virus vaccine is also available. Vaccination of cattle with sheeppox virus, also attenuated by passage through tissue culture, is effective in preventing infection with the lumpy skin disease virus and is currently the most common method of protection. A small percentage of cattle develop granulomatous local reactions but there is no spread of the sheeppox to sheep running with the cattle. Vaccination of a herd at the start of an outbreak has limited efficacy as most animals will already be incubating the disease. Poor needle hygiene in these circumstances may spread the disease.

Cattle vaccinated with a recombinant capripox-vinferpest vaccine are immune to experimental challenge with both viruses but for a different length of time with each agent. Slaughter of infected and in-contact animals and destruction of contaminated hides, coupled with vaccination of at-risk animals, is used when the disease gains access to a previously free country.

REFERENCES

VIRAL PAPULAR DERMATITIS
This disease of horses occurs in the United States, United Kingdom, and Australia. It is a contagious disease characterized by cutaneous lesions in the form of firm papules 0.5–2 cm in diameter. No vesicles or pustules are formed, but after 7–10 days a dry crust is detached, leaving small circumscribed areas of alopecia. The lesions are not itchy, there is no systemic disease and the distribution of the lesions, and the way in which they can develop simultaneously in large numbers in introduced horses, is suggestive of an insect-borne disease.

The course of the disease varies between 10 days and 6 weeks. An unidentified virus has been isolated from lesions and cultured on eggs. A febrile reaction, up to 40.2°C (104.5°F), precedes the appearance of skin lesions by about 24 hours. There is no histological description. Recovery is usually complete and uncomplicated. The disease is clinically similar to molluscum contagiosum in horses associated with poxvirus. This disease has similar papular lesions, which are hypopigmented and covered by tufts of raised hair but the disease has a long clinical course. Histologically, these show proliferation of keratinocytes containing large intracytoplasmic inclu­sions, known as molluscum bodies, which are composed of numerous pox virions.
COWPOX

**Synopsis**

**Etiology** Cowpox virus is a member of the genus *Orthopoxvirus* in the family Poxviridae. Other orthopoxviruses infecting agricultural animals include horsepox, Uasin Gishu, buffalopox and camelpox. All orthopoxviruses are antigenically extremely similar, but they can be identified by a combination of phenotypic and genetic tests.

**Epidemiology**

Occurrence

Cowpoxvirus could be considered to be misnamed. Infection with this virus is endemic in wild rodents such as voles (*Microtus* spp.) in Great Britain, Europe and western Asia, with infection in different rodent species acting as the reservoir host in different geographic areas. Domestic cats are commonly infected from hunting rodents, but cowpoxvirus infection can occur in a number of different mammalian species, one of which is cattle. The clinical syndrome of cowpox in cattle is now extremely rare but it occurs sporadically in Europe. Seroprevalence in British cattle is less than 1%.

Origin of infection and transmission

The origin of infection is most probably from infected farm cats or humans. Transmission from cow to cow within a herd is effected by carriage on milkers’ hands, and may spread to the insides of the thighs, and rarely to the perineum, vulva and mouth. Sucking calves may develop lesions about the mouth. In bulls, lesions usually appear on the scrotum.

**Clinical findings**

Typical pox lesions on the teats and udder. Erythema, papules with a zone of hyperemia around the base, vesiculation, pustular stage and scab.

**Clinical pathology**

Electron microscopy

**Diagnosis**

Electron microscopy and virus isolation

**Treatment**

Palliative

Sanitation to prevent spread between cows

**Economic importance**

Losses are due to inconvenience at milking time because of the soreness of the teats and from occasional cases of mastitis, which develop when lesions involve teat sphincters. Milk from affected cows is suitable for human consumption.

**Zoonotic implications**

Human cowpox is not common and usually consists of one or a few lesions on the hand and face with minimal systemic reaction. Infection is more likely to come from an infected cat than cattle.

**Pathogenesis**

In cowpox, the five stages of a typical pox eruption can be observed. After an incubation period of 3–6 days, a roseolar erythema is followed by firm, raised papules light in color but with a zone of hyperemia around the base. Vesiculation, a yellow blister with a pitted center, follows. The subsequent pustular stage is followed by the development of a thick, red, tenacious scab.

In experimentally produced vaccinia virus mammaritis (produced by inoculation of smallpox vaccine), the lesions have three zones: a central brown crusty area of necrosis, surrounded by a gray-white zone of microvesicle formation, again surrounded by a red border due to congestion. The lesions are essentially hyperplastic.

**Clinical findings**

Typical lesions may be seen at any stage of development, but are mostly observed during the scab stage, the vesicle commonly having been ruptured during milking. True cowpox scabs are 1–2 cm in diameter and are thick, tenacious, and yellow-brown to red in color. In cows being milked, scab formation is uncommon, the scab being replaced by a deep ulceration.

Distribution of the lesions is usually confined to the teats and lower part of the udder. Soreness of the teats develops and milk letdown may be interfered with; the cow usually resents being milked. Secondary mastitis occurs in a few cases. Individual lesions heal within 2 weeks, but in some animals fresh crops of lesions may cause the disease to persist for a month or more. In severe cases, lesions may spread to the insides of the thighs, and rarely to the perineum, vulva and mouth.

**Control**

Prevention of spread is difficult, since the virus responsible for the disease is readily transmitted by direct or indirect contact. Udder cloths, milking machines and hands should be disinfected after contact with infected animals. Dipping of the teats in an alcoholic tincture of a suitable disinfectant, such as quaternary ammonium compounds, is usually satisfactory in preventing immediate spread. The prevalence and significance of the disease in cattle is too low to warrant the development of vaccines.

**Pseudocowpox (Milkers’ Nodule)**

**Synopsis**

**Etiology** Parapox virus

**Epidemiology** Primarily affects cows in early lactation. Low, but progressive, morbidity in herd. Spread during milking

**Clinical findings** Vesicles, pustules, formation of a thick scab elevated by
ETIOLOGY

Pseudocowpox virus is a member of the genus *Parapoxivirus*, with close similarity to the viruses of infectious papular stomatitis and contagious ecthyma. It is possible that *Parapoxivirus* may be a single virus adapted to different species of ruminants.

EPIDEMIOLOGY

Occurrence

Pseudocowpox is reported from most countries. In an affected herd the rate of spread is relatively slow and may result in the disease being present in the herd for up to a year. The morbidity rate approximates 100%, but at any given time varies between 5 and 10%, and occasionally up to 50%.

Origin of infection and transmission

The source of infection is *infected cattle*. The method of transmission includes physical transport by means of contaminated milkers’ hands, wash cloths, and teat cups. The virus cannot penetrate mucosa, and a pre-existing discontinuity of it is necessary for the virus to gain entry. Transmission by biting insects seems likely. The virus can be isolated from the mouths of calves sucking affected calves, and from the semen of bulls.

Animal risk factors

Freshly calved and recently introduced cattle are most susceptible, but all adult cattle in a herd, including dry cows, are likely to be affected. The disease does not appear to occur in animals less than 2 years of age unless they have calved. There is no seasonal variation in incidence. Little immunity develops and the disease is likely to recur in the herd within a short time.¹

Economic importance

Pseudocowpox is relatively benign, most losses occurring as a result of difficulty in milking and an increase in the incidence of mastitis.

Zoonotic implications

The disease is transmissible to humans, infection usually resulting in the development of milker’s nodule on the hand.

PATHOGENESIS

The disease can be reproduced by the introduction of the virus onto scarified areas of skin. The lesions are characterized by hyperplasia of squamous epithelium.

CLINICAL FINDINGS

Acute and chronic lesions occur, and there may be up to ten lesions on one teat. Acute lesions commence as erythema followed by the development of a vesicle or pustule, which ruptures after about 48 hours, resulting in the formation of a thick scab. Pain is moderate and present only in the pre-scab stage. The scab, varying in size from 0.5 to 25 cm in diameter, becomes markedly elevated by developing granulating tissue beneath it; 7–10 days after lesions appear the scabs drop off, leaving a **horseshoe-shaped ring** of small scabs surrounding a small, wart-like granuloma, which may persist for months. The disease tends to disappear from a herd after 18–21 days but may recur cyclically about 1 month later. There are reports of lesions occurring occasionally in cows’ mouths.

**Chronic lesions** also commence as erythema, but progress to a stage in which yellow-gray, soft, scurfy scabs develop. The scabs are readily rubbed off at milking, leaving the skin corrugated and prone to chapping. There is no pain and the lesions may persist for months.

**Milkers’ nodules** are clinically indistinguishable from human lesions associated with ecthyma virus. The lesions vary from multiple vesicles to a single, indurated nodule.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Material for examination by tissue culture or electron microscopic examination, the latter being highly recommended as a diagnostic procedure, should include fluid from a vesicle.

TREATMENT

Locally applied ointments of various kinds appear to have little effect on the spread of the disease. An iodophor teat dip is recommended as the most effective control measure. An effort should be made to reduce teat trauma because infection is facilitated by discontinuity of the skin.

BOVINE ULCERATIVE MAMMILLITIS (BOVINE HERPES MAMMILLITIS)

ETIOLOGY

The causative virus, *bovine herpesvirus-2* (BHV-2), is an alphaherpesvirus. Infection with BHV-2 can produce two distinct syndromes in cattle, *bovine herpes mammillitis* where there are vesicular and erosive lesions with necrotic ulceration on the skin of the udder and teats and pseudo-lumpy skin disease (Allerton virus) manifest with generalized superficial skin lesions over the body. Pseudo-lumpy skin disease is uncommon. The difference in clinical manifestations between the two diseases may be due to the strain of the virus, or the method of infection. BHV-4 (DN599 strain), which is usually associated with respiratory disease in cattle, is also capable of causing mammary pustular dermatitis.¹

EPIDEMIOLOGY

Occurrence

Herpes mammillitis is recorded in North America, Australia, Europe and Africa, but probably has widespread occurrence. Herds infected for the first time have a high morbidity rate. Subsequently, the incidence is low and is limited to fresh
heifers. The morbidity rate varies between 18 and 96%, susceptible herds recording more than 30% affected. The mortality rate is negligible.

Origin of infection and transmission
Introduction of bovine ulcerative mammillitis into a herd may occur with the introduction of infected animals, but outbreaks have been observed in self-contained herds. Spread within the herd is probably by direct and fomite-mediated transmission, although experimentally the virus must be deposited in the deep layers of the skin, and even rubbing it into pseudocowpox lesions is not an efficient way of transmitting the disease. Milking machine liners, hands, and udder cloths may act as carriers of virus when a large amount of it is being released.

Seasonal and circumstantial evidence in the United Kingdom and Australia suggest an insect vector, but this has not been confirmed by attempts at transmission with the stable fly (Stomoxys calcitrans), and in the mid-west of the United States, disease is more common in the winter months between November and April. Survival of the virus for long periods in carrier animals occurs and it is thought that this may be the means of survival of the virus within a herd that has become immune. Infection in some cows is suspected to result in chronic infection at the teat end with the cows becoming "hard milkers" and carriers of the disease.

Animal and pathogen risk factors
Lesions are most common in animals within the first 2 weeks after calving, particularly in heifers, and the disease is more severe in heifers. Heifers that have udder edema at calving are particularly prone to develop severe lesions. Occasionally, lesions may be seen on the teats of replacement heifers and calves sucking infected dams often develop mouth lesions.

The disease is usually self-limiting, persisting in a herd for 6–15 weeks, the severity of the lesions decreasing as the outbreak progresses. Immunity appears to last about a year, herds infected naturally persisting in a herd for up to 1 year, herds infected naturally may have recurrences a year later. Large herds may have persistent disease, particularly in heifers.

The virus is relatively resistant to environmental influences and can survive freezing. It is susceptible to iodophor disinfectants and less so to hypochlorites.

Economic importance
Forms of loss include a much higher incidence of mastitis, reduction in milk in affected herds by up to 20%, the culling of some cows because of severe mastitis and of heifers because of intrac-table ulcers, and a great deal of interference with normal milking procedure.

Zoonotic implications
There are anecdotal reports of herpetic lesions in farmers exposed to infected cattle.

PATHOGENESIS
Typical clinical lesions and histopathological changes can be produced locally by introduction of the virus into scarifications of the skin of the teat and the oral mucosa, and by ID and IV injection. There is no viremia and spread is by local extension. In contrast to the poxes, the characteristic lesion in mammillitis is destructive. The higher incidence of the disease and the greater severity of the lesions close to calving are thought to be due to the immunosuppression caused by parturition and to greater predisposition from peri-parturient udder edema.

CLINICAL FINDINGS
There is an incubation period of 5–10 days. There is no systemic illness, and lesions are confined to the teats and udder. When the disease occurs in a herd for the first time the first case is usually in a cow that has calved during the previous 2–3 days. Rapid lateral spread then occurs to other cows.

In cows calved more than a few weeks previously, the characteristic lesions are almost entirely confined to the skin of the teats; in recently calved cows they are restricted to the skin of the teats and the udder. The severity of the disease in recently calved cattle appears to be directly proportional to the degree of postparturient edema which is present. Vesicles occur but are not commonly seen. They are characteristically thin-walled, 1–2 cm in diameter, variable in outline, and often commence at the base of the teat and spread over much of the udder surface. Rupture and confluence of the vesicles leads to weeping and extensive sloughing of the skin.

In the most severe cases, the entire teat is swollen and painful, the skin is bluish in color, exudes serum and sloughs, leaving a raw ulcer covering most of the teat. In less severe cases, there are raised, deep red to blue, circular plaques, 0.5–2 cm in diameter, which develop shallow ulcers. In most cases, scab formation follows but machine milking causes frequent disruption of them, resulting in frequent bleeding. The least severe lesions are in the form of lines of erythema, often in circles and encircling dry skin or slightly elevated papules, which occasionally show ulceration. Mild lesions tend to heal in about 10 days but severe ulcers may persist for 2 or 3 months. The severity of lesions on the teats on longer-calved cows varies, but in all cases the lesions are sufficiently painful to make milking difficult. Lesions on the skin of the udder heal more rapidly because of the absence of trauma.

Ulcers in the mouth of affected cows have been observed rarely, and calves sucking affected cows develop lesions on their oral mucosa and muzzles. Ulcerative lesions on the vaginal mucosa have been recorded rarely. During the recovery phase there is obvious scar formation and depigmentation.

The generalized skin disease associated with BHV-2, 'pseudo-lumpy skin disease' is discussed in the differential diagnosis of lumpy skin disease.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS
Material for tissue culture, electron microscopy, or cutaneous transmission tests is best obtained by syringe from early vesicles, or as swabs from early ulcers or oral lesions. The virus may be difficult to demonstrate if the lesions are as old as 7 days, and if there has been intensive application of teat disinfectants such as iodophors.

Serology is more commonly used for diagnosis. The presence of high virus-neutralizing antibody titers in serum taken during the acute phase of the disease, and a four-fold increase or decrease in titer in paired samples, are all supportive for diagnosis. Titters of 1:16 or higher for BHV-2 and 1:20 for BHV-4 indicate exposure. Antibody to both viruses should be tested for diagnostic purposes.

Necropsy is not commonly performed and no necropsy reports of cases of bovine ulcerative mammillitis are available.

DIFFERENTIAL DIAGNOSIS

<tbody>
<tr>
<td>Differentiation of other diseases of the skin of the teat and udder</td>
<td>dealt with in the section on cowpox</td>
</tr>
</tbody>
</table>

TREATMENT
There is no specific treatment and the aim should be to develop scabs that can withstand machine milking. This is most easily effected by the application of a water-miscible, antiseptic ointment just before putting the cups on, followed by an astringent lotion, such as triple dye, immediately after milking. Crystal violet dyes have an excellent reputation as treatments.

CONTROL
Isolation of affected animals and strict hygiene in the milking parlor are practiced but have little effect on the spread of the disease, nor does milking heifers first. An iodophor disinfectant is recommended.
for use in the dairy to prevent spread. Reducing the incidence and severity of periparturient edema in heifers may reduce the severity of herpes mammillitis. Inoculation of the natural virus away from the teats produces a local lesion and good immunity, but the method has not been tested as a control procedure.

**REVIEW LITERATURE**

**REFERENCES**

**SHEEPPOX AND GOATPOX**

**Synopsis**

**Etiology** Capripoxvirus. Strains vary in virulence and host specificity

**Epidemiology** Highly contagious, spread by aerosol, contact and flies. Young and non-indigenous animals more susceptible. Morbidity and case fatality rates are high

**Clinical findings** Fever, generalized skin and internal pox lesions, lymphadenopathy, mucopurulent nasal discharge, high mortality

**Clinical pathology** Fluorescent antibody and electron microscopy of biopsy material, serology, virus isolation

**Necropsy findings** Pox nodular lesions in alimentary and respiratory tract

**Diagnostic confirmation** Fluorescent antibody staining, virus isolation

**Control** Vaccination

**ETIOLOGY**

Three viruses are named on the basis of natural occurrence. Recombination may produce are also collectively called capripox infections. The diseases they produce are as described above for the benign form of the disease. Pathogen risk factors

**Epidemiology** Occurrence and prevalence of infection

Sheeppox and goatpox are prevalent in North and Central Africa, the Indian subcontinent, Middle Eastern countries, China, Southwest Asia and the former Soviet Union. Sporadic outbreaks occur in southern Europe and elsewhere. The capripoxvirus infections of small ruminants are the most serious of all the pox diseases in animals. In susceptible flocks and herds morbidity is 75–100% with outbreaks often causing death in 10–85% of affected animals depending on the virulence of the infecting strain.²⁻⁹

**Methods of transmission**

Sheeppox and goatpox are highly contagious. The virus enters via the respiratory tract and transmission commonly is by aerosol infection associated with close contact with infected animals. The virus is present in nasal and oral secretions for several weeks after infection and can live in scabs that have fallen off the animal for several months. Spread can also occur from contact with contaminated materials and through skin abrasions produced iatrogenically or by insects. Capripox has been shown to spread via the bites of Stomoxys calcitrans and the tsetse fly.¹⁰

**Experimental reproduction**

The disease can be transmitted by intradermal, intravenous and subcutaneous inoculation and by virus aerosols.

**Risk factors**

Animal risk factors

Both sheep pox and goat pox affect sheep and goats of all ages, breeds and sex but young and old animals and lactating females are more severely affected. In areas where sheeppox is enzootic, imported breeds such as Merinos or some European breeds may show greater susceptibility than the native stock.

**Young animals** are more susceptible.

**Pathogen risk factors**

The virus is resistant to drying and survives freezing and thawing. It is sensitive to extremes of pH and 1% formalin. Sensitivity to heat varies between strains but most are inactivated at 60°C for 60 min. Isolates from most regions are host specific but isolates from Kenya, Yemen and Oman naturally infect both goats and sheep. Scabs shed by infected animals remain infective for several months.

**Economic importance**

Loss is from mortality, abortions, mastitis, loss of wool, skin condemnation and loss of exports. In ewes and does, severe losses may occur if the udder is invaded because of the secondary occurrence of acute mastitis. In some outbreaks, adult sheep are affected with the more severe form of the disease.¹¹ Sheeppox is a potent threat to countries that have big sheep populations, and where the disease does not occur, because of its ieradicability and heavy mortality rate.

**Zoonotic implications**

Human infections in people handling infected animals are not a consideration.²⁻⁹

**PATHOGENESIS**

During an initial viremia, the virus is deposited in most tissues, including the skin. The development of typical pox lesions, as in vaccinia, is characteristic of the disease. The virus is present in greatest quantities between the 7th and 14th day after inoculation. Passive protection by serum will protect against challenge. Circulating antibody limits spread of infection, but does not prevent replication of virus at the site of inoculation.

**CLINICAL FINDINGS**

In sheeppox in sheep there is an incubation period of 12–14 days. In lambs, the malignant form is the most common type. There is marked depression and prostration, a very high fever and discharges from the eyes and nose. Affected lambs may die during this stage before typical pox lesions develop. These, when they develop, occur on unwooled skin and on the buccal, respiratory, digestive, and urogenital tract mucosae. They commence as papules, then become nodular, occasionally become vesicular, pustular and finally scab. Some progress from nodules to tumor-like masses.¹¹ The mortality rate in this form of the disease may reach 50%. In the benign form, more common in adults, only skin lesions occur, particularly under the tail, and there is no systemic reaction and animals recover in 3–4 weeks. Abortion and secondary pneumonia are complications. Goatpox in sheep is more severe than sheeppox, and lesions occur on the lips and oral mucosa, the teats and udder.

**Goatpox** in goats is very similar clinically to sheeppox in sheep. Young kids suffer a systemic disease, with lesions spread generally over the skin, and on the respiratory and alimentary mucosae. Adult goats may have systemic disease and extensive lesions,⁷,⁹ but in adult goats the disease is usually mild and lesions are as described above for the benign form in sheep. A flat hemorrhagic form of capripox is seen in some European goats and this has a high case fatality.

**CLINICAL PATHOLOGY**

**Antigen detection**

Diagnosis is based on typical clinical signs combined with laboratory confirmation of the presence of the virus or antigen. Using electron microscopy, large numbers of characteristic ‘sheeppox cells’ containing inclusion bodies and typical capripox virions can be seen in biopsies of the skin. The virus can be cultured in tissue culture but virus isolation as a method of rapid
diagnosis is limited by the time it takes for virus cytopathic effects to develop and the need, with some strains, for several blind passages before this develops. Direct fluorescent antibody test is used to detect the presence of pox virus in the edema fluid and the antigen can be detected in biopsies of lymph glands by AGID using specific immune sera. An antigen detection ELISA is also available.

Serology
In India a soluble antigen fraction, which is non infectious, has replaced infectious virus for serological tests which avoids the risk of accidental spread of the virus from diagnostic laboratories and from the postal supply of diagnostic agents. However, serological tests such as AGPT, serum neutralization and agar gel diffusion are confounded due to cross reaction with other virus. A capripox-specific capture-ELISA is reported to have sufficient sensitivity, specificity and speed to have utility in rapid diagnosis using biopsy samples. Serological testing can be by virus neutralization, which is specific or by an indirect fluorescent antibody test or an agar gel precipitation (AGPT), however both of the latter cross react with antibody to contagious pustular dermatitis virus. Virus-specific analysis of antibody response by Western blot analysis can differentiate the infections.

A capripox PCR for detection of antigen is used in some countries which do not have the disease and do not hold live virus.

NECROPSY FINDINGS
In the malignant form, pox lesions extend into the mouth, pharynx, larynx, and vagina with lymphadenopathy and a hemorrhagic spleen. Lesions may also appear in the trachea. Lesions in the lung are severe manifesting as lentil sized white pox nodules to a consolidating necrotizing pneumonia. Lesions occasionally reach the abomasum and are accompanied by a hemorrhagic enteritis.

DIFFERENTIAL DIAGNOSIS
- Contagious ecthyma (orf)  
- Bluetongue.

TREATMENT
No specific treatment is advised, but palliative treatment may be necessary in severely affected animals.

CONTROL
Control is achieved by worldwide eradication and containment of infected flocks.

SWINEPOX

Clinical findings
Characteristic pox lesions mainly on skin of head, legs and belly.

Clinical pathology
Demonstration of typical lesions by histology and virus by electron microscopy.

Lesions
Typical pox lesions.

Diagnostic confirmation
Demonstration of typical lesions by histology and virus by electron microscopy.

Treatment
None.

Control
Control of hog louse.

ETIOLOGY
The cause is swinepox virus, the sole member of the Sapovirus genus of Chordopoxvirinae subfamily of Poxviridae.

EPIDEMIOLOGY
Occurrence
Swine pox (pig pox) occurs worldwide where swine are raised and is more common in swine units where there is poor sanitation.

Methods of transmission
Transmission is by contact transmission and mechanically by the pig louse (Haematopinus suis), and possibly by flies and other insects. Young sucking pigs may have lesions on the face, with similar lesions on the udder of the sow, with spread by direct contact. The virus can survive in scab material for several months.

Animal risk factors
The virus infects only swine and can infect all ages but clinical disease is most commonly seen in young piglets. It is usually a sporadic disease with occasional outbreaks affecting a cluster of litters within a herd and of short duration. Some or all pigs in a litter may show clinical signs. The disease may appear apparently spontaneously or may occur only in pigs brought into the contaminated environment of a herd in which the indigenous pigs are immune.

The incidence in individual herds may be high. Mortality is usually low except in very young piglets and congenitally affected piglets where mortality rates can be high. Congenital infection presents with a low morbidity but high case fatality. Older animals seem to suffer little ill effect.

PATHOGENESIS
In field cases, the lesions progress through the classical phases of poxvirus infections but do not usually proceed past the pustular or vesicle stage. At this time there is rupture and the formation of scabs which heal and drop off. Congenital infection presents with a low morbidity but high case fatality. Older animals seem to suffer little ill effect.
fetal membranes. Not all fetuses are born affected and compartmentalization of placentas may restrict further uterine spread as occurs with parovirus infections.3

CLINICAL FINDINGS
Small 1 to 1.5 cm diameter papules develop first and may pass through the pustular and vesicular stage very quickly with the formation of red-brown, round scabs. In neonatal pigs, the rupture of many vesicles at one time may cause wetting and the fetal membranes. Not all fetuses are born affected and compartmentalization of placentas may restrict further uterine spread as occurs with parovirus infections.3

Affected piglets were born from healthy sows. Affected piglets may be stillborn or die within a few days after birth. CLINICAL PATHOLOGY
The diagnosis is confirmed by examination of skin biopsies.2 Focal superficial erosions, marked epidermal hyperplasia with acanthosis, ballooning of epidermal cells, and occasional large eosinophilic intracellular inclusion bodies are present on histological examination.3,4,5 Electron microscopy can be used to detect the viral particles and the virus can be cultivated in primary pig kidney cell tissue culture.2,4,5

DIFFERENTIAL DIAGNOSIS
The distribution of the pox-like lesions and their association with the disease with louse infestations suggest the diagnosis. Swinepox may resemble swine vesicular disease, which is characterized by vesicles on the coronary bands, lips, tongue, and snout. Lesions associated with Tyrophysllus spp. mites are usually larger and occur anywhere on the body, and like those of sarcoptic mange, are usually accompanied by itching. The causative mites are detectable in skin scrapings. Ringworm and pythiosis cause similar lesions that do not itch, occur in older pig than typically does swine pox, and fungal spores are present in scrapings in the former disease. A vesicular disease with necrosis resembling swine pox has been attributed to infection with parovirus7 but there is little evidence that parovirus is a primary skin pathogen.8

TREATMENT
No specific treatment is available and lesions cause so little concern to the pig, and heal so rapidly, that none is attempted.

CONTROL
Vaccination is not usually practiced and control of the pig lice is the principal prophylactic measure attempted in most outbreaks.

REFERENCES

HORSEPox
Horsepox is a benign disease characterized by the development of typical pox lesions either on the limbs, or on the lips and buccal mucosa.1 The causative poxvirus is identical to the virus of true cowpox and is transferable to cattle and to humans. Infection of a foal by cowpox was associated with streptococcal septicemia and death.2 Horsepox is rare. It is a benign disease, but badly affected horses become debilitated and occasionally young animals may die. It is spread by contact with infected grooming tools, harness, and by handling. Immunity after an attack is solid.

Typical pox lesions develop in a 'leg form,' or in a 'buccal form'. In the 'leg form' nodules, vesicles, pustules, and scabs develop, in that order, on the back of the pastern and cause pain and lameness. The wound care may hasten healing. Because there is no specific treatment and no control methods are reported.

REFERENCES

ULCERATIVE DERMATOSIS OF SHEEP
Ulc erative dermatosis of sheep is an infectious disease characterized by the destruction of epidermal and subcutaneous tissues, and the development of raw, granulating ulcers on the skin of the lips, nares, feet, legs, and external genital organs. The lesions on the lips occur between the lip and the nostril, on those on the feet occur in the interdigital space and above the coronary, and the genital lesions occur on the glans and the external opening of the prepuce of rams, and the vulva of ewes.

A virus, very similar but antigenically different to the ethyema virus, is the cause of the disease, which is likely to be confused with contagious ethyema. However, the lesions are ulcerative and destructive rather than proliferative as in ethyema. It is not highly infectious like bluetongue or sheeppox, and the 'lip-and-leg' distribution of the lesions differentiates it from balanoposthitis of wethers, strawberry foot rot, foot rot, and interdigital abscess. The presence of lesions on the glans penis, and their absence from mucosa, the typical ulcerative form of the lesion, the absence of pus and the susceptibility of recovered animals to infection with ethyema virus are diagnostic features of ulcerative dermatitis.
A morbidity rate of 15–20% is usual, but up to 60% of a flock may be affected. Mortality is low if the sheep are in good condition and the lesions are treated. Physical contact at breeding time seems to be the most probable method of spread.

The lip cutaneous form of this disease is very rare and possibly has disappeared since its original description, or is very uncommon. A clinically similar disease to the genital infection of ulcerative dermatitis, with balanoposthitis and vulvovaginitis, is associated with Mycoplasma mycoides.\(^1\)

**REFERENCE**

### Diseases associated with Chlamidiae

The Phylum Chlamidiae consists of obligate intracellular bacterial pathogens and contains four families of which two have members that are associated with animal disease. A different family within the Chlamidiae contains Waddlia chondrophila that has been isolated from aborted fetuses.

The prominent farm animal and horse diseases associated with Chlamydiales are chlamydial polyarthritis (\(Cp.\) pecorum) and chlamydial abortion (\(Cp.\) abortus) which are described below, and sporadic bovine encephalomyelitis (\(Cp.\) pecorum) which is described elsewhere under that heading. \(Cp.\) pecorum may also be an
etiological agent in some outbreaks of ovine contagious ophthalmia which is described under that heading.

Other infections and possible diseases associated with these agents and with C. suis and C. pneumoniae are less commonly reported although it is possible that they underdiagnose.¹

The standard method of diagnosis of chlamydial disease is by isolation in embryonated eggs or in cell culture. However, some strains are difficult to grow and require specialist facilities and expertise. Also the complement fixation test, which is the standard serological test for chlamydial disease, lacks sensitivity and specificity because of cross reaction between chlamydial species.¹ The organisms are obligate intracellular pathogens and depend on the host cell for energy in the form of adenosine triphosphate (ATP). Outside of the host cell they exist as metabolically inactive elementary bodies, which have a rigid cell wall and are unable to grow or divide. The elementary bodies attach to host cells and are taken in by phagocytosis. Inside the phagosome they become the metabolically active reticulate body (initial bodies), which have flexible cell walls and grow and divide to form an intravacuolar microcolony called a chlamydial inclusion. Nascent elementary bodies are formed, the host cell is lysed, and the elementary bodies are released with the cycle being accomplished in 36 to 96 hours, depending on species. The current development of new and more sensitive and specific molecular and serological tests such as PCR and the use of recombinant major outer membrane proteins as antigens can allow species specific laboratory diagnosis and should allow a better definition of the importance of C. pecorum and C. pneumoniae and C. suis to agricultural animal disease.¹²

**REPRODUCTIVE DISEASE**

In addition to enzootic abortion in ewes Chlamydiaceae have been associated with reproductive inefficiency in swine and cattle.

In swine, infection with C. pecorum and C. abortus have been associated with increased rates of returns to estrus, abortion, mumification, stillbirth and increased perinatal and neonatal mortality. Some studies of swine in herds with and without a problem of early embryonic death have found no significant difference in the seroprevalence of antibodies to Chlamydiaceae but have found a significant difference in the presence and proportion of C. abortus in cervical swabs and in the uterus and oviducts at slaughter. A dual infection with C. suis was also demonstrated in some cervical swabs in these studies but, whereas an association of C. abortus and reproductive inefficiency was evident, the contribution of C. suis to reproductive inefficiency was less clear.³⁻⁵

Reports of reproductive inefficiency in swine are largely from Germany and Switzerland, but in large industrial piggeries in eastern European countries, in addition to being implicated in severe outbreaks of abortion and production of
weak piglets, infections with Chlamydiae are reported to produce reproductive disease in boars, polyarthritis and polyserositis in young pigs, arthritis in finishing pigs, and pneumonia and conjunctivitis. In contrast other studies suggest that chlamydial infections are endemic in pigs and that the significance of Chlamydiae as pathogens in swine remains to be determined.7

In cattle, C. abortus is a cause of bovine abortion but much less commonly than in small ruminants and not causing enzootic disease. Infertility and endometritis in cattle has been associated with the organism and has been reproduced experimentally.8 However, there is debate as to the importance of Chlamydiae as major reproductive pathogens in cattle as non-clinical infection of the reproductive tract is common. A recent study using PCR found a high (53%) prevalence of C. abortus and C. pecorum infection in the vagina of virgin heifers.8 A subsequent study established that infection occurred in calves at a very young age. In this study, C. pecorum infection was fivefold more prevalent than C. abortus infection and was most frequently detected by vaginal swabs compared to rectal or nasal swabs.10

Waddlia chordophila was initially isolated from an aborted calf in the USA and has subsequently been demonstrated in aborted fetuses in other countries. Serological studies suggest that it might have a role in the causation of bovine abortion. Free living amoeba may serve as hosts.11–13

OTHER DISEASE ASSOCIATIONS

C. suis has been associated with enteric disease in pigs but is also present in the intestines of clinically normal finishing and adult pigs.3,14

C. suis has also been associated with respiratory disease in swine and this has been reproduced experimentally in conventional pigs by aerobic challenge.15

C. psittaci has also been demonstrated in domestic and wild pigs (Sus scrofa).16,17 Other miscellaneous occurrences are cases of pneumonia in most animal species, including horses,18 cattle, sheep, goats and pigs, and orchitis and epididymitis in male ruminants and intestinal infections in ruminants and pigs.19,20 It is not possible to classify the Chlamydiae associated with some of these reports. The horse respiratory isolate is closely related to human isolates of C. pneumoniae.21 Enteritis and diarrhea in calves, from which C. pecorum can be isolated, are usually mixed infections and the pathogenicity of the chlamydiophila as a cause of enteritis is open to doubt.

REFERENCES

Chlamydia pneumoniae, chlamydiophila, and renal abscess. Clinically, the disease is indistinguishable from polyarthritis caused by other infections such as Mycoplasma and Haemophilus spp.

REVIEW LITERATURE

REFERENCES

CHLAMYDIAL POLYARTHRITIS

Virulent chlamydia, including Chlamydia pecorum, can be isolated from the joints of calves, lambs, and foals clinically affected by polyarthritis. The experimental disease in calves begins as a chlamydemia, followed by localization in the joints. In calves, the disease is uncommon but often fatal. In lambs, it is a common disease in sheep feedlots in the United States, but the mortality rate is low.4 The strain associated with arthritis is not common in the United Kingdom2 and polyarthritis in the UK has been associated with a chlamydial strain distinct from C. pecorum.5

In pastured sheep, the morbidity may be as high as 80% but deaths are usually less than 1%. In calves, the disease is more commonly sporadic but response to treatment is poor and affected calves are often destroyed on humane grounds. Intestinal infection with Chlamydia pecorum is common in pastured lambs between 3 and 9 months of age, but is not associated with clinical disease.4

The clinical signs in calves and lambs include gross swelling of most limb joints but especially the larger joints, lameness, stiffness, unwillingness to move, recumbency, depression, conjunctivitis, and fever of 39–42°C (102–108°F). The navel is unaffected but there may be signs caused by localization of the infection in other organs, e.g. pneumonia, encephalomyelitis, and renal abscess. Clinically, the disease is indistinguishable from polyarthritis caused by other infections such as Mycoplasma and Haemophilus spp.

ETIOLOGY

Chlamydia abortus (previously Chlamydia psittaci biotype1/serotype1) has a tropism for ruminant placenta and causes the disease commonly referred to as ovine enzootic abortion (OEA). The organism causes a similar disease in goats, and while this organism also can produce abortion in cattle, pigs and horses, abortion associated with this organism is not common in these species.

There is considerable genetic diversity amongst strains that cause abortion.1,2

EPIDEMIOLOGY

Occurrence

The disease is one of the commonest causes of diagnosed abortion in sheep and goats in the United Kingdom, the United States,3 and in other countries. In the UK it accounts for approximately 45% of abortions, and it is particularly common in lowland flocks that are intensively
managed at lambing time. However, its importance varies from country to country. It is an uncommon cause of abortion in Northern Ireland, and the disease does not occur in Norway or New Zealand.

There have been several studies of seroprevalence in Europe which show a high seroprevalence in both domestic and wild ruminants but, until recently, most surveys have used the complement fixation test which is not specific for C. abortus and the seroprevalence rates for C. abortus in different countries are not well established.

Source of infection and transmission
Infection is introduced into a flock by the purchase of latently infected replacements which usually abort at the end of their first pregnancy.

Within a flock, the major source of infection is the placenta and the uterine discharge of aborting ewes. The main routes of transmission of C. abortus are through ingestion of organisms shed in vaginal fluids and placental membranes at the time of abortion or lambing, or through inhalation of aerosols from the environment. Pasture and the environment are contaminated by vaginal discharges, placenta and aborted fetuses, and infected ewes shed the organism for a week before aborting and for 2 weeks afterwards. The elementary body of C. abortus is resistant to both physical and chemical influences as it is metabolically inactive and the rigid cell envelope is osmotically stable and poorly permeable. As a consequence the organism is believed to survive for several days on pasture and longer in cold weather.

Infection of the ewe lamb may occur at birth, shortly following, or at subsequent lambing periods. Infection of pregnant ewes in early or mid gestation results in either abortion in the final 2–3 weeks of gestation, or the birth of stillborn or weak lambs that frequently die in the first few days of their life. Abortion always appears in the last weeks of gestation regardless of the time of infection. Infection of ewes in the last 5–6 weeks of pregnancy usually leads to the development of a latent infection, where ewes appear to be uninfected until the next lambing season, when they abort. Thus, late pregnant sheep may be infected by contact with aborting ewes but usually do not themselves abort until the next lambing season.

The common pattern of infection and disease is the a small number of abortions in year 1 usually resulting from the introduction of infected replacement ewes, followed by an epidemic abortion storm where up to 35% of ewes abort in the last 3 weeks of gestation or give premature birth to weak or dead lambs. After abortion, the ewes develop a protective immunity and, in endemically infected flocks, 5–10% of the ewes abort annually. Surviving lambs born to infected mothers may be affected by EAE in their first pregnancy.

Sheep that have aborted, subsequently re-breed successfully, do not have further abortions, and the organism is not present in the placenta or vaginal discharge of subsequent pregnancies. However, levels of immunity vary and some may excrete organisms at estrus or seasonally for up to 3 years.

In chronically infected sheep, persistent infection can be demonstrated in the endometrial cells of the reproductive tract, and the organism is excreted in vaginal fluids during estral periods. Vaginal challenge of ewes at breeding time will result in infection and subsequent abortion, and venereal or passive venereal transmission is a possible route of infection, but it does not appear to be a common or important route. Chronic infection of the male genital tissues has been recorded and infection may impair fertility in both rams and bulls.

The epidemiology of abortion with this agent in cattle is unknown but it may transmit to cattle from infected sheep on the same farm.

Experimental reproduction
The disease is readily reproduced experimentally. Following subcutaneous injection there are no signs of clinical disease other than a modest increase in rectal temperature for two days after infection. There is a systemic antibody response that peaks 2 weeks after infection and then decreases until just before abortion or parturition, when there is a second increase in the antibody levels to C. abortus. Experimental infection at 70 to 75 days pregnancy can result in abortion in the last 2 to 3 weeks of pregnancy or the birth of stillborn or live lambs. There is variation in the severity of the placental lesions in experimental infections. Abortion is associated with severe placental lesions but the reason for the variation in severity and fetal manifestations is not known.

Economic importance
Enzootic abortion is the most common infectious cause of abortion in lowland flocks that are intensively managed at lambing time, and has a major economic impact on agricultural industries worldwide. There are no recent estimates of economic impact but losses in the UK were estimated in the early 1990s at £15–20 million per annum.

Zoonotic implications
There is some risk for shepherds, and those in allied fields such as abattoir workers, to contract respiratory infection with this organism but the major zoonotic risk is to pregnant women because of the ability of C. abortus to colonize the human placenta. Human infection in early pregnancy results in abortion whereas later infection can result in stillbirth or pre-term labor. Infection is believed by the oral route from infected hands or food following direct handling of infected sheep or goats or infected clothing. Practices at lambing such as mouth to mouth resuscitation of weak lambs or bringing weak lambs into the house to be warmed promote zoonotic spread. Infected placentas and dead lambs should be handled using gloved hands and disposed of by burning or burial.

The organism can be detected in milk both in sheep and in cattle and raw milk could also pose a risk for zoonotic infection.

PATHOGENESIS
Following infection, it is thought that the organism resides first in the tonsil, and is then disseminated by blood and lymph to other organs although the site of latent infection is not known. The latent state is maintained under the control of the proinflammatory cytokine interferon-gamma (IFN-γ). Release from the latent state during pregnancy is believed due to immune modulation and leads to bacteremia and infection of the placenta.

The organisms invade the trophoblast cells of the fetal cotyledon following which infection spreads to the intercotyledonary regions of the chorion to produce a supplicative necrotic placentalitis with impairment of the maternal–fetal exchange of nutrients and oxygen and fetal death and abortion. An inflammatory response in the fetus may also contribute to fetal death.

It is not known why, regardless of the time of infection, pathological changes in the placenta do not commence before 90 days gestation or even as late as 120 days.

CLINICAL FINDINGS
There are generally no premonitory indications of the impending abortions. Abortion occurs in late pregnancy; ewes appear to suffer no systemic effects, but retained placenta and metritis can be sequel in goats. Additional losses are caused by stillbirths and weak-born lambs and kids which die soon after birth.

A vaginal discharge lasting up to 3 weeks following the abortion is common.
In cattle, the infection causes abortion in the last third of pregnancy. Infected calves born alive may show lethargy, depression, and may be stunted.

**CLINICAL PATHOLOGY**

Infection in aborting animals can be demonstrated serologically by rising titers in paired serum samples and by culture of the organism.15

The complement fixation test is commonly used to identify flocks free of infection. It has moderately good sensitivity but is not specific for the agent of due to a common antigen shared by all members of the family and also to some Gram-negative bacteria.22 For samples testing positive, a Western blot examining for antibody against specific antigens can be used as a reference test in flock accreditation.23 **ELISA tests**, based on whole cell chlamydial elementary bodies or extracts of them, have better specificity than the complement fixation test but poorer sensitivity. A comparison of tests in common use in the United Kingdom in the mid 1990s found that none were both highly sensitive and specific.23 **ELISA tests** that are based on segments of the membrane outer protein or synthetic peptide antigens have greater sensitivity and specificity and are now used in diagnostic, epidemiologic and seroprevalence studies.22,24,25

**NECROPSY FINDINGS**

Aborted fetuses typically have no gross abnormalities. Fetal fluid may contain chlamydophilial antibody and although less sensitive than either isolation in McCoy cells or detection of chlamydial LPS antigen, can be of particular use when placenta is not available. Histologically, there may be mononuclear cell infiltration of hepatic portal areas and multifocal areas of hepatitis. In both cattle and sheep, the placenta critical for diagnosis of the condition. Placental cotyledons are necrotic and hemorrhagic, and the intercotyledonary areas are thickened, edematous, and leathery. This is in direct contrast to the targeting of cotyledons seen with toxoplasmosis. The *Chlamydia* organisms can be observed in tightly-packed sheets within the cytoplasm of swollen trophoblasts in formalin-fixed tissue samples, or in direct placental smears via modified Gimenez, Koster’s, or other appropriate staining methods. Well-preserved, fresh placenta should be examined as the organisms are difficult to demonstrate in the fetus. Immunohistochemical stains perform well on formalin-fixed specimens. Most laboratories are reluctant to culture *Chlamydia* spp. due to the zoonotic potential of these agents.

**Samples for confirmation of diagnosis**

- **Bacteriology** – chilled liver, lung, placenta (CYTO, PCR, ELISA)
- **Histology** – fixed placenta, liver (LM, IHC)

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

**DIFFERENTIAL DIAGNOSIS**

Other causes of abortion in cattle and ewes are given in (Tables 18.7 and 18.8).

**CONTROL**

Ewes that have aborted should be isolated from the rest of the flock. There should be proper hygiene of the lambing areas and in the disposal of abortal materials. Tetracycline has been used in early pregnant sheep within an aborting flock to attempt to reduce subsequent abortions but the efficacy is questionable.

**Vaccines**

Two types of vaccine are currently available but there is yet no vaccine that has excellent efficiency against this disease.

- **Killed vaccines**, composed of egg-grown or tissue culture grown organisms of one or two strains have been used for several decades. They are variably effective and can reduce the frequency of abortion and the shedding of the organism. However, outbreaks have occurred in vaccinated sheep and strain variation is a possible cause of failure of monovalent vaccines.1

The addition of Freund’s incomplete adjuvant has provided a vaccine that provides better protection26 and it has been recently claimed that specific adjuvants can markedly improve the efficiency of killed vaccines against naturally occurring enzootic abortion.27,28

A **live vaccine** containing a temperature-sensitive attenuated strain of *C. psittaci* has shown to engender excellent, but not complete, protection against challenge; with five different abortigenic strains of *C. abortus* there was a marked reduction in the number of ewes aborting and marked increase in live-born lambs compared to controls.29 It is labeled for sheep but not for goats. Concern has been expressed for the zoonotic potential of an attenuated vaccine.27

Recombinant and DNA vaccines have shown disappointing protection in studies with experimental challenge.30,31

Diseases associated with prions

INTRODUCTION

The transmissible spongiform encephalopathies (TSEs) are a group of progressive neurological disorders that are transmissible and affect a number of animal species and humans (Table 23.1). They are non-febrile with long incubation periods and a long course of disease.

There is debate of the nature of the infective agent causing TSEs. An abnormal folded isoform, designated PrPSc, of a host encoded cell-surface glycoprotein (prion protein, PrPC) accumulates during disease and is associated closely with infectivity. The function of PrPC is not known and the mechanism whereby PrPSc is converted to PrPSc is uncertain. PrPSc is rich in β sheets and can be isolated as insoluble aggregates. A theory is that the transmissible agent is the abnormal isoform of the prion protein and that, in the infected host, this can recruit further alternatively folded prion protein. With this theory the long incubation period of prion diseases reflects the rise in level and deposition of PrPSc in a variety of tissues, including brain, eventually resulting in fatal spongiform encephalopathy.

Scrapie affects sheep and goats and is the prototypic disease for the group. Although scrapie in sheep has been recognized for over 200 years the recent epidemic of bovine spongiform encephalopathy has focused public attention and scientific research on the TSEs. With scrapie, and other TSEs, transmission can be effected by crude or purified extracts of brain or other tissues from affected animals, and the infective agent is very resistant to ionizing and ultraviolet irradiation and to reagents that damage or modify nucleic acids. This, along with other experimental findings, has led to proposals that the infectious agent in scrapie, and other TSEs, is the PrPSc itself, and not a small, unconventional virus or viroin as previously proposed. The structure of the infecting PrPSc is believed to imprint upon the normal cellular precursor PrPC, resulting in a change to the abnormal isoform which is protease-resistant and accumulates in cells.

Naturally occurring TSEs, such as sporadic CJD in humans or transmissible mink encephalopathy in mink, are associated with individual species or with closely related species as with scrapie in sheep, goats and mouflon (Ovis musimon) and chronic wasting disease in mule deer (Odocoileus hemionus), white-tailed deer (Odocoileus virginianus) and elk (Cervus elaphus nelson). The results of attempts at inter-species transmission of these diseases are variable. While, by definition, each TSE is transmissible, the species to which they will transmit varies between the TSE, and can be influenced by the route of challenge, and the tissues that contain infection also varies according to the particular TSE. Frequently they do not transmit. Successful primary transmission between different mammalian species typically requires larger dose to effect disease than would be required for transmission to the same species. Also, usually, parenteral or intracerebral routes are required and success is greater with young animal recipients. This is the so-called ‘species barrier’, which may be absolute or partial in that it will affect only a proportion of animals on first passage, or may result in an extended incubation period on first passage.

When using transmission studies to detect the presence of one of these agents optimal sensitivity is with a recipient host the same species. Transgenic mice may eliminate this barrier.

The ‘gold-standard’ technique for the diagnosis of TSE agents is the passage of tissue in panels of inbred mice, a technique known as ‘strain typing’. Until recently this was the only way to differentiate scrapie and BSE. BSE presents with a characteristic incubation period, pattern of distribution and relative severity of the changes in the brain of the different mouse strains – the lesion profile – which is distinct from all scrapie strains tested to date.

When examining TSEs as a group, one cannot extrapolate the transmission particulars of one TSE to another nor can one extrapolate risk factors or epidemiology from one to another and certainly generalizations from an experimental model to a natural disease across a species barrier is scientifically inappropriate.

The literature on this subject is large. This chapter will discuss scrapie in sheep and goats, and bovine spongiform encephalopathy, which are the two TSEs of agricultural animals. It will also discuss the risk for BSE in sheep, particularly as this is a current cause for concern.

<table>
<thead>
<tr>
<th>Synopsis</th>
</tr>
</thead>
</table>
| **Etiology** | A transmissible agent that is highly resistant to chemical and physical agents, and appears not to contain DNA. Proposed to be due to a prion, a proteinaceous infectious particle. Susceptibility of sheep determined by genetics.
| **Epidemiology** | Transmitted primarily by contact with infected sheep and from environmental contamination; very long incubation period.
| **Clinical findings** | Non-febrile disease of adult sheep and goats with insidious onset and long clinical course. Affected animals show behavioral change, tremor, pruritus and locomotor disorder, and wasting.
| **Clinical pathology** | Demonstration of scrapie prion protein by immunostaining of lymphoid tissue.
| **Lesions** | Vacuolation of gray matter neuropil and neuronal perikarya, neuronal degeneration, gliosis.
| **Diagnostic confirmation** | Demonstration of scrapie prion protein.
| **Treatment** | None.
| **Control** | Slaughter eradication. Genetic testing and selection/culling. Selection/culling based on detection of scrapie prion protein in lymphoid tissue.

Scrapie is a non-febrile, fatal, chronic disease of adult sheep and goats, characterized clinically by pruritus and abnormalities of gait, and by a very long incubation period. It is the prototypic disease for a group of diseases known as transmissible spongiform encephalopathies. This group also includes chronic wasting disease of deer and elk, transmissible mink encephalopathy, and feline spongiform encephalopathy, Creutzfeldt–Jakob disease and other spongiform encephalopathies of humans, and the relatively new disease, bovine spongiform encephalopathy, which is described separately under that heading. In Iceland scrapie is known as *rida*, in France as *la tremblante* and in Germany as *Traberkrankheit*.

**Etiology**

There has been a significant historical debate over the etiology of this disease, centered on whether the disease is inherited or associated with an infectious agent, and centered also on the nature of the infectious agent. Currently, it is believed that scrapie is associated with an infectious agent, but that the incubation period for clinical manifestation of the disease and the susceptibility of the host is determined by genetics.

Scrapie can be transmitted experimentally to other sheep and to certain laboratory animals, and infection induces the production in the brain, and some other tissues, of amyloid fibrils called scrapie-associated fibrils or prion rods. The main constituent of these is a disease-specific, protease-resistant neuronal membrane glycoprotein termed the prion protein, or PrPSc. PrPSc is an abnormal isoform of a host-coded membrane glycoprotein, PrPc, and the transmissible spongiform encephalopathies are characterized by the accumulation of PrPSc in neuronal and other tissue.

Transmission can be effected by crude or purified extracts of brain or other tissues from affected sheepr and the infective agent is very resistant to ionizing and ultraviolet irradiation and to reagents that damage or modify nucleic acids. This, along with other experimental findings, has led to proposals that the infectious agent in scrapie is PrPSc itself, and not a small, unconventional virus or virino as previously proposed. The structure of the infecting PrPSc is believed to imprint upon the normal cellular precursor PrPc, resulting in a change to the abnormal isoform which is protease-resistant and accumulates in cells. The experimental studies and the arguments for this are reviewed elsewhere.

More than 20 different strains of scrapie have been identified based on:

- Strain typing by differences in incubation time of the experimental disease in inbred strains of mice of different genotype.
- The type, pattern, severity, and distribution of lesions in the brain of different strains of experimental animals (lesion profiles).
- Resistance to thermal inactivation.
- The type of disease produced in sheep and experimental animals (e.g. drowsy versus pruritic manifestations in goats).

- The ability of a strain to produce disease in different species of experimental animals.

It is proposed that strain differences reflect differences in replicating information carried within the conformational state of the PrPSc.

Co-infection can occur with scrapie. It is common for more than one strain to infect sheep but since one will have a shorter incubation period, it will predominate and be expressed first. The masked strains can be revealed by passage in different mice strains.

**EPIDEMIOLOGY**

**Occurrence**

Geographic occurrence and incidence: Scrapie in sheep occurs enzootically in the United Kingdom, Europe, and North America. Outbreaks have been reported in Australia, New Zealand, India, the Middle East, Japan, and Scandinavia, primarily in sheep imported from enzootic areas. Australia and New Zealand used vigorous importation, quarantine, and culling policies to prevent subsequent entry of the disease and are considered free of disease.

The true prevalence of the disease both within and between countries is not known as there has been no test to detect the presence of infection in individual sheep or in flocks at all stages of infection. This is further confounded by secrecy about its existence in many flocks and breeds. This secrecy results from a fear of economic penalties that could result from the admission of infection.

In Great Britain, where the disease is enzootic and has been recognized for over 250 years, the true incidence is unknown, although a questionnaire survey in 1988 suggests that one-third of sheep flocks are infected. In infected flocks the annual incidence ranges from 0.4 to 10 cases/100 sheep per year, with a mean of 1.1 cases/100 sheep per year. However, the annual incidence can approach 20% of the adult flock 10%, on occasions up to 40%, and in flocks where there is no selection against the disease the annual incidence and mortality can reach a level that results in disbandment of the flock or its non-survival.

However, there is a difficulty in determining the occurrence of scrapie with any accuracy. In Britain, subsequent to the survey mentioned above, a large survey in 1998 found 15% of flocks reporting a case of scrapie sometime in the past, with 2.7 reporting a case in the past year. The authors of this survey, and of a subsequent follow-up survey which gave even lower numbers of flocks infected, believe that the disease is grossly underreported, despite the fact
that scrapie has been notifiable in Britain since 1993.

Farmer-consultation with a veterinarian about a case of scrapie and farmer-reporting of cases of scrapie is notoriously low. Historically, this has been due to factors such as the stigma associated with having scrapie diagnosed in a purebred flock and concerns for future sales or, in the case of commercial flocks, a lack of incentive to consult and a lack of concern since nothing can be done to cure the present case or prevent future cases. In England, it has been estimated that only 13% of farmers who had a suspect case of scrapie in the past 12 months reported it. Possibly, the chance of improvement through genetic selection will alter this farmer trait.

The limitation of postal survey responses and their reliance on the recognition and diagnosis of scrapie by the farmer, coupled with the farmers reluctance to notify scrapie has prompted targeted surveillance using fallen stock and abattoir surveys throughout Europe. For most European countries, this targets a random sample of 6000 fallen sheep and 60,000 routinely slaughtered adult native sheep and uses the cattle-validated rapid tests.

The determination of the spatial occurrence of scrapie at the holding (farm) level is important in view of current thrusts at control and eradication. Surveillance of fallen stock is relatively efficient but has a low capture rate for infected holdings and abattoir surveys also show a lack of sensitivity.

It has been observed that scrapie-infected flocks show a scrapie signature, in which older sheep with genotypes at greater risk for scrapie are under-represented, and it has been proposed that this signature could be a way of identifying infected flocks. This observation has not been validated by other studies and, for a scrapie signature to operate, it would require loss from scrapie to outweigh all other causes of attrition of older ewes in a flock and a relatively constant ram-allele input. The latter would be unlikely given ram turn over and variation in ram working lifespans.

In the United States, the disease is believed to have been introduced in 1947, and between 1947 and 1992 was found in 657 flocks in 39 states.

Host occurrence

Age

Scrapie is a disease of mature sheep although most are exposed as young sheep and the incidence decreases with age at exposure. The age-specific incidence in sheep is highest between 2.5 and 4.5 years of age and cases rarely occur under 18 months of age. Natural disease in goats is rare. The age at death is similar to that in sheep, with a range from 2 to 7 years. The case fatality rate, with time, is 100%. The death loss is added to by the slaughter of infected and in-contact animals in countries where control and eradication is a practice.

Breed

Scrapie occurs in both sexes and in the majority of breeds, although the incidence is higher in some breeds than others. Breed differences in prevalence occur in several countries; an example would be the high prevalence in the Suffolk breed in the United States relative to white-faced breeds and in some Hill breeds in the UK. These probably reflect breed and flock differences in genetic susceptibility to the development of clinical disease. Similarly, the occurrence of outbreaks of scrapie may result from the introduction of infection to a genetically susceptible flock or to a change in the genetic structure of flocks that are infected.

Methods of transmission

Knowledge of transmission of scrapie is based primarily on the experimental disease and observations of the natural disease in experimental flocks and has been reviewed.

Sources and routes of infection

The usual method of introduction into unaffected flocks is by the purchase of pre-clinically infected sheep. Infectivity can be demonstrated in the placenta and fetal fluids of naturally occurring cases, but has not been demonstrated in the saliva, colostrum, milk, urine or feces of natural cases, even though it can be demonstrated in the intestine and nasal mucous membrane. Ingestion of infected material appears the most likely route of infection, but scarification of the skin and conjunctival inoculation will also allow infection. Hay mites have been found to harbor the agent on scrapie infected properties and have been proposed as a reservoir for infection.

Horizontal transmission

This is the usual method of spread and the placenta is considered the major source of infection for the mother to her lamb, and to other lambs in close contact. Under natural conditions the disease in flocks often runs in families, and whether or not a lamb contract scrapie appears to depend primarily on the current or future scrapie status of its dam. It is common for all the VQR/VQR lambs from dams dying of scrapie to themselves develop scrapie.

Scrapie can also transmit between sheep in close contact and this can occur from sheep in the preclinical phase of the disease.

Vertical transmission

There is a greater risk for scrapie in lambs born to infected dams but this most probably reflects horizontal transmission at birth from placetas. There are conflicting results between studies that have examined transmission by embryo transfer, and the importance of vertical transmission to the epidemiology of the natural disease remains to be determined. However, epidemiological studies suggest that it is of rare occurrence and there is significant evidence against the occurrence of in-utero transmission. The agent has not been demonstrated in the testes or semen of rams.

Environment

An infected environment can also be the source, and scrapie-free sheep can develop disease after grazing pasture previously grazed by scrapie-infected sheep, with infection by ingestion or possibly via abrasive lesions. Environmental infection can occur from the products of parturition and, although the scrapie agent has not been demonstrated in feces, it is suspected as being so in infected animals. The duration of infectivity on inanimate materials such as pastures has not been defined, but field and experimental observations suggest that it is a long time, probably in excess of 3 years. A paired case-control study of risk factors in 61 scrapie affected flocks in Ireland found increased odds of scrapie occurring in flocks associated with the spreading sheep compost on the pasture and disposing of the placenta in the compost.

Iatrogenic transmission

An outbreak of scrapie occurred in the 1930s following the use of a vaccine against louping ill prepared from the brains of sheep. More recently, the use of a vaccine against contagious agalactia has been epidemiologically linked to an outbreak of scrapie in sheep and goats in Italy where there was a high attack rate and high mortality affecting several birth cohorts.

Genetics

Scrapie is recorded in most breeds of sheep but there are breed, family, and individual differences in susceptibility. There is substantial genetic control of the
incidence of disease, and in both the natural and experimental disease, genetics is a major determinant of susceptibility with the susceptibility of sheep strongly linked to certain polymorphisms in the sheep PrP gene.2,3

In earlier studies, experimental challenge and breeding showed that sheep could exhibit a long or short incubation period following challenge and that this difference in incubation period or susceptibility was determined by a single gene called Sip (scrapie incubation period). There is a similar gene in mice (Sinc) that determines incubation period and susceptibility following experimental challenge. The Sip gene has two alleles, SA and pA, which respectively shorten or prolong the experimental incubation period for most strains of the scrapie agent. The subsequent recognition of prion protein (PrP) and its association with scrapie led to the recognition of the gene that encodes PrP which was found congruent to Sip in sheep and Sip genetics have been entirely superseded by PrP genetics.2

Sheep have one pair of genes that influence susceptibility to scrapie known as the prion protein genes. These code for a normal prion protein in the cell (PrPc), which has 254 amino acids with each codon in the gene encoding for a specific amino acid at a particular location on PrPc. PrPc can be converted to scrapie prion protein molecule (PrPSc) in infected sheep which, when it accumulates in the central nervous system, causes disease. The susceptibility of sheep to this conversion, and thus to scrapie, is strongly associated with certain polymorphisms at codons 136, 154, and 171. It is thought that there are at least two groups of scrapie TSE strains, one of which is influenced primarily by the amino acid at codon 136 and the other group by the amino acid at codon 171. Within these there may be subtypes, as resistance to some 136-type TSEs can be affected by the amino acid at codon 154.3,4

- At codon 136 valine (V) is linked to scrapie susceptibility and alanine (A) is linked with resistance
- At codon 154 histidine (H) is linked to susceptibility and arginine (R) to resistance
- At codon 171 glutamine (Q) and histidine (H) are linked to susceptibility and arginine (R) to resistance

Of the possible alleles from these polymorphisms only five, ARR, ARQ, VRQ, AHQ, ARH, are commonly seen and the relationship between PrP genotype and susceptibility to scrapie is shown in Table 23.2 using the groupings of the British National Scrapie Plan. It can be seen from Table 23.2 that in the Britain, the VQR allele confers the greatest degree of susceptibility and that ARR is associated with resistance. Estimates that quantify risk in the British national flock based on genotypes of the sheep, and those of scrapie affected sheep are available but they are not strongly concordant.6,7 There is also an effect of PrP genotype on incubation period with the most susceptible genotypes (VQR) having the shortest incubation period and dying of scrapie at a younger age.

The frequency and distribution of the various PrP genotypes varies considerably between flocks and between breeds of sheep.2,3,7

For example, in 15 flocks scrapie-affected flocks, the flock frequency of sheep with VQR-containing genotypes ranged from 2 to 82%.7

Adapted from Refs 7 & 17.
There are also some marked between-breed differences in susceptibility with the same PrP genotype.\textsuperscript{27} Susceptibility in the Suffolk breed appears less complex than in other breeds and is strongly associated with sheep that are homozygous for glutamine at the 171 codon (171QQ) of the PrP gene but is rare in sheep heterologous for glutamine and arginine (171QR) or homozygous for arginine (171RR) at codon 171.\textsuperscript{35} Suffolks are the predominant breed affected with scrapie in the USA. They lack the VRQ allele and the ARQ/ARQ genotype is the genotype that confers the greatest susceptibility.\textsuperscript{24,26,27,34} The association between genotype and susceptibility as defined in the scrapie eradication plan of the USDA in the USA is shown in Table 23.3.

Factors other than the PrP genotype influence susceptibility to scrapie as not all sheep with a susceptible genotype challenged with scrapie subsequently develop the disease. Also there are some breed differences in the level of resistance or susceptibility conferred by a given genotype. For example ARQ/ARQ Suffolk sheep are highly susceptible to scrapie whereas ARQ/ARQ Cheviots relatively resistant. Breed differences in PrP genotype scrapie disease linkage and disease pattern differences with atypical strains of scrapie may be associated with polymorphisms in the PrP gene promoter.\textsuperscript{35}

There is little information on the genetics of scrapie in goats. There is high variability in the goat PrP gene which possibly can be exploited to select for goat-specific scrapie-resistant PrP genotypes but as yet these are not known.\textsuperscript{36}

There is a dose–response relationship in naturally occurring scrapie.\textsuperscript{30} The high incidence in some Icelandic flocks is attributed to a high level of exposure, resulting from a long winter housing period with a higher risk for disease in lambs born in the winter housing period.

Factors that influence exposure risk will vary with the management systems, which can vary markedly between countries. With that caveat, risk factors that have been identified in case control studies\textsuperscript{3,28,37} include:

- A higher risk for scrapie in larger flocks and in pedigree flocks.
- A greater risk in flocks that lamb communally in group pens compared to those that in those that lamb in individual pens or outside on pasture.
- A greater risk in flocks that disposed of the placenta in the compost and spread sheep compost on the land.
- A lower risk in flocks where cow compost is spread on the land.
- A greater risk in flocks that purchased replacement sheep through the market.
- A greater risk where different flocks share pastures or rams.

**Age at exposure**

Lambs exposed at birth have a shorter incubation period and higher risk for scrapie than lambs exposed at 6–9 months of age. Similarly, lambs or goats removed from infected dams at birth to a scrapie-free environment have a lower incidence of scrapie than those removed at later times.

**Infection status of parents**

Lambs born to affected ewes are at increased risk for scrapie, and the offspring from an infected ewe and an infected ram are at greater risk than those born from an infected ewe and an uninfected ram. However, even in high-incidence herds a considerable proportion of disease cannot be attributed to parental scrapie status and results from horizontal transmission.\textsuperscript{10} Also the number of genetically susceptible sheep in an affected flock can increase the infection pressure.

**Goats**

**Scrapie in goats** is rare and most cases arise in goats that are in close contact with infected sheep. Scrapie can spread from goat to goat with no sheep contact.\textsuperscript{18}

**Experimental reproduction**

The agent is present in the brain, spinal cord, lymph nodes, intestinal tract tissue, and spleen of infected sheep, and has been extracted from sheep and goat brain. Experimentally, the disease can be transmitted to sheep, goats, mice and other laboratory animals using these tissues, and by a variety of routes of inoculation. The experimental disease has a long incubation period that varies with the strain of the agent and the genetics of the recipient. Transmission of the disease to sheep has also been effected by the oral or intracerebral administration with fetal membrane material from known infected ewes. Accidental transmission is recorded following vaccination against loping-ill, with vaccine contaminated by the agent of scrapie, and resulted in widespread dissemination of the disease.

**Pathogen risk factors**

The scrapie agent can be maintained in tissue culture, and infectivity is retained with passage.\textsuperscript{21} It can also be perpetuated in experimental animals. Infectivity also survives for remarkable periods in dead and formalinized tissues; infected brain homogenates buried in soil for 3 years retain their infectivity.\textsuperscript{26} It is highly resistant to physical and chemical influences and can survive decontamination processes that are effective against conventional viruses.\textsuperscript{38} It is capable of withstanding the usual virucidal procedures and is not destroyed by boiling, by rapid freezing and thawing, or by exposure to ether or 20% formalin. Conventional heat treatments may reduce infectivity, but the agent is remarkable resistant to heat\textsuperscript{39} and steam sterilization at 27 psig (132°C) is required to totally destroy it. Chemical inactivation can be achieved with sodium hypochlorite providing 2% (20 000 ppm) of available chlorine acting for 1 hour, and by 4% sodium hydroxide.

**Economic importance**

Scrapie is of major concern to pedigree flocks and, if present and public, will curtail the sale of sheep and effectively result in the dissolution of the flock. Some countries have, or have had, eradication schemes. The disease is also of major international importance because of the embargos maintained by several countries against sheep from enzootic areas. The recent occurrence of bovine spongiform encephalopathy in Great Britain and one theory of its putative origin from scrapie has emphasized the need for control of this disease.

**Zoonotic implications**

There is no evidence for transmission of scrapie to humans or for a risk to public health.\textsuperscript{40} However the concern that BSE might be established in sheep as a result of feeding of infected meat-and-bone meal, and be indistinguishable from scrapie, has led some countries to establish an active TSE surveillance program in sheep. As part of this, all sheep that are over 18 months of age and intended for human consumption are tested at slaughter by a rapid test for scrapie and BSE.

**PATHOGENESIS**

In both sheep and mice, the agent shows a predilection for tissues of the lympho-
reticular system where it replicates during the incubation period before invading the nervous system. In naturally infected sheep, replication begins in the tonsil, retropharyngeal and Peyer's patches and gut-associated lymphoid tissue, which probably reflects the oral route of infection. PrPSc subsequently becomes disseminated to other lymph nodes and the spleen. There may be a considerable period, ranging from 14 months to 7 years, before there is infection of the brain, and during this period in the lymphoreticular system probably provides the reservoir for maternal and horizontal transmission. 24,41,42 The action of the PrP genotype may be to delay neural invasion, in which case it is possible that a non-clinical carrier state may exist for scrapie. 43

How the scrapie agent reaches the central nervous system is not certain but is probably through infection of the autonomic nervous system. Gut-associated lymphoid nodules in the Peyer's patches have a substantial network of nerve fibers and are probably the site for neuroinvasion and the scrapie agent has been detected in lymphoid nodules of the Peyer's patches of the gut as early as 5 months after oral infection. 44

Infection in the brain of sheep is initially in the diencephalon and medulla oblongata, with subsequent spread and replication in other areas of the brain. Characteristically, there is a non-inflammatory, vacuolar degeneration of gray matter and the presence of PrPSc in scrapie-associated fibrils. Infection results in the post-translational modification of this protein so that it becomes resistant to proteinases and to normal clearance and consequently accumulates in the cell.

PrPSc is also present in the placenta and is present in the trophoblast cells of the placentomes but not in the endometrium, myometrium, associated nerve plexuses nor is it in fetus. The presence of PrPSc in the placenta is determined by the fetal PrP gene and PrPSc is not present in the placenta of fetuses carrying one or two ARR alleles. 24,34

**CLINICAL FINDINGS**

**Incubation**

The incubation period varies from several months to several years. Scrapie is a non-febrile disease and the onset is insidious, but as the disease progresses clinical signs become more obvious and severe. The clinical course is protracted, varying from 2 to 12 months, but lasting in most cases for about 6 months. Affected animals usually show behavioral change, tremor, pruritus, and locomotor disorder.

**Early signs**

The earliest signs are transient, nervous phenomena occurring at intervals of several weeks or under conditions of stress. These episodes include sudden collapse and sudden changes of behavior, with sheep charging at dogs or closed gates.

Rubbing and biting at the fleece then begin but are often unobserved because of their infrequent occurrence. The apparent pruritus is manifested chiefly over the rump, thighs, and tail base. The poll and dorsum of the neck may also be involved and, less commonly, the neck in front of the shoulder and the ribs behind the elbow. The affected areas have approximate bilateral symmetry. In this early stage a stilted gait is often observed. A general loss of condition may also be observed as an early sign, although the appetite may not be severely affected.

**Advanced cases**

**More advanced cases** show intense pruritus, muscle tremor and marked abnormalities of gait, and severe emaciation. **Persistent rubbing** causes loss of wool over the areas mentioned above. Scratching with the hindfeet and biting at the extremities also occur. Hematoma of the ears and swelling of the face may result from rubbing. Light or deep pressure, pinpricking, and application of heat or cold may elicit the characteristic 'nibbling or scrapie scratch' reaction, during which the animal elevates the head and makes nibbling movements of the lips and licking movements with the tongue. The sheep's expression suggests that the sensations evoked are pleasant ones. The reaction may not be observed consistently, often disappearing when the sheep is excited or in new surroundings.

Simultaneously with the development of pruritus there is serious impairment of locomotion. Hindlimb abnormalities appear first. There is incomplete flexion of the hock, shortening of the step, weakness, and lack of balance. The sense of spatial relationship appears to be lost and the sheep is slow to correct abnormal postures. Abduction occurs during extension, and abduction during flexion. When the animal is attempting to evade capture, gross incoordination of head and leg movements is likely and the animal often falls. Convulsions, usually transient but occasionally fatal, may occur at this time.

General hyperexcitability is evident. In the animal at rest an intermittent nodding and jerking of the head and fine tremor of superficial muscles may also be observed. In some cases, nystagmus can be produced by rotating the head sideways. Other clinical signs include inability to swallow, although pneumonia is unaffected, vomiting, loss of blood, and blindness. A change of voice to a trembling note is often most noticeable.

Anorexia is not evident in most cases until the last 4–5 weeks and results in rapid loss of body weight. Abomasal distension and impaction occurs in some cases. Pregnancy toxemia may occur as a complication in pregnant ewes during this stage of scrapie. Finally, the sheep reaches a stage of extreme emaciation and inability to move without becoming readily fatigued. Ecteral recumbency follows and lateral recumbency with hyperextension of the limbs is the final stage. Pyrexia is not evident at any time.

In a detailed study in 129 sheep with scrapie the proportional occurrence of signs was: hindlimb ataxia 71%; head tremor 61%; altered mental status 57%; positive nible reflex 51%; crouching position 51%; teeth grinding 44%; low head carriage 38%; body condition score of less than 1.5, 38%; and consciousness proprioceptive deficits of limbs 36%. 45

**In goats,** the clinical course in naturally occurring cases lasts from 2 to 24 weeks. Clinical signs are similar to those in sheep, and hyperesthesia, ataxia and pruritus are common, but loss of weight is less common. 22 In lactating goats the first sign may be a reluctance to permit milking. Dribbling and regurgitation of ruminal contents are also recorded in one-third of cases.

In most countries the disease is reportable to government authorities.

**CLINICAL PATHOLOGY**

There are no changes in hematologic or serum biochemistry parameters. It has been suggested that the disease could be diagnosed antemortem by electroencephalography but this has been disputed. 42

Until recently there has been no antemortem test for scrapie; however, PrPSc can be detected in cells by immunohistological methods and is present in the lymphoid tissue of sheep with scrapie in the preclinical phase of the disease.

**Tonsillar biopsy** has detected PrPSc in lambs of susceptible genotypes as young as 5 months of age 46 and in the tonsils of non-challenged susceptible lambs at 9–10 months of age that were born and maintained in a scrapie environment. 47 However, tonsil biopsy requires general anesthesia and is not a practical on-farm technique. Biopsy of lymphoid follicles in the third eyelid is more practical, requires only restraint and local anesthesia, and can be a valuable tool for the preclinical diagnosis of scrapie in surveillance programs. 48

In scrapie positive sheep, PrPSc can usually be detected by 14 months. A sample of a single protuberance on the
A mathematical model of the program has examined the time it would take to eliminate scrapie from the national flock and individual number. The model assumes that the disease is geographically clustered and that the disease can be individually identified with a unique identifier. The model suggests that investing money in the early stages of the program will be a good investment, as it is less expensive to prevent the disease than to treat it later. The model also indicates that the program should be voluntary, as mandatory programs have been less successful in eliminating the disease. The model predicts that the program will be successful in virtually eliminating the disease from the country, but it may take decades to do so.

The maintenance of a closed flock is critical to the control of this disease. If ewes need to be purchased from outside the flock, they should be from similar farms that are free of the disease. The process of selecting and screening ewes is crucial to the success of the program, as new strains of the disease can emerge from imported animals.

Individual flocks

The occurrence of scrapie and the concern over BSE in sheep has led many countries to develop national programs to control the disease. The National Scrapie Plan in the UK was introduced in 1998, and the National Scrapie Plan in the USA, Canada, and Australia were introduced in 1999. These plans have been successful in controlling the disease, and the incidence of scrapie has declined dramatically since the introduction of the plans.

The essential histopathological lesion in scrapie is the vacuolation of grey matter neuropil in the spinal cord. The essential histopathological lesion in BSE is the vacuolation of the cerebral cortex. The essential histopathological lesion in scrapie is also a hallmark of the disease, and it is used to diagnose the disease.

ments of identification and reporting it is not based on genetic testing.

The USA also has a USDA Genetics Based Flock Clean-Up and Monitoring Plan. This program targets scrapie infected and source flocks. The sheep in these flocks are genotyped, sheep with susceptible genotypes are removed (as are all goats) and the flock is placed under surveillance for five years. Flocks that are exposed to scrapie are placed on a monitoring program and if scrapie is detected would begin the genetics based clean up program. The eyelid biopsy test can be used for selected monitoring for preclinical disease in these flocks.48

There is concern that breeding for the selection for certain PrP genotypes and reduction or elimination of other PrP genotypes could affect other desirable genetic characteristics and reduce the overall 'genetic pool'. This will need to be determined for individual breeds but preliminary analyses, that have involved several breeds, suggest that reproductive traits, muscle mass, wool quality, live weight gain, carcass characteristics, is not affected, at least in some breeds.56-58

There has also been concern that rare breeds could be threatened in the face of an occurrence of scrapie and flock with subsequent disposition of the flock based on PrP genotype. Interestingly there is a good representation of ARR with some breeds having very high frequencies.59

REVIEW LITERATURE

REFERENCES

BOVINE SPONGIFORM ENCEPHALOPATHY (BSE)

Bovine spongiform encephalopathy (BSE) is an afibrile neurological disorder affecting adult cattle. It is a subacute transmissible spongiform encephalopathy and is believed due to a single stable cattle-adapted strain of a scrapie-like agent and occurred as the result of the exposure of cattle to animal protein feeds containing the scrapie agent.

The disease is of considerable importance mainly because it has zoonotic potential and has spread to many countries. The cost of control is very high.

ETIOLOGY

BSE is a prion-associated transmissible spongiform encephalopathy. The stability of the lesion profile in cattle and the lesion profiles in mice strongly suggests that the epidemic in Britain, and the subsequent extended epidemic in other countries, is due to a single stable cattle-adapted strain of a scrapie-like agent.1 There is debate as to whether the transmissible agent is a strain of scrapie that has modified to infect cattle or whether it originated from a sporadic spongiform encephalopathy pre-existent in the cattle population. There is evidence of characteristics that distinguish it from conventional scrapie strains.2,3 In view of the high susceptibility of certain African ungulates and zoo carnivores to infection it has also been postulated that the agent could have entered into meat-and-bone meal from the carcass of an animal that died in a zoo or a safari park in the UK.4 A further hypothesis promotes meat and bone meal from the Indian sub-continent as a source. The British government has conducted several enquiries into the source of the agent and the cause of the outbreak including the Phillips report in 2000,5 and the Horn report in 2001 but there has been no conclusion and the source may never be known.

The mass exposure of cattle in Great Britain to this agent, and the subsequent development of a disease epizootic in cattle in the latter half of the 1980s and the early 1990s is believed to have been the consequence of a change in the method of processing of meat-and- bone meal (MBM) prepared from slaughterhouse (or
cattle) latently infected with the agent so as to allow it to persist in this feed.9-8

Subsequent recycling of the agent in meat-and-bone meal prepared from latently infected slaughter cattle amplified its occurrence.

**EPIDEMIOLOGY**

**Occurrence**

**Geographic occurrence**

BSE was first described in Great Britain in 1987 but the BSE Inquiries considered it likely that there had been several undetected cycles of BSE in the South West of England in the 1970s and early 1980s. Following its description in 1987, the disease developed to an epizootic with over 183,000 cases, of which more than 95% were detected before 2000. The epidemic peaked at an annual total of more than 37,000 clinical cases in 1992. The disease was recognized in Northern Ireland, in 1998 and in the Republic of Ireland in 1999. The disease was subsequently recognized in Switzerland, Portugal and France in the early 1990s and is now widespread.

Cases have occurred in imported British cattle in Oman and the Falkland and Channel Islands Countries that have had cases of BSE in native cattle are Austria, Belgium, Canada, Czech Republic, Denmark, Finland, Germany, Greece, Ireland, Italy, Japan, Luxembourg, Netherlands, Poland, Portugal, Slovakia, Slovenia, Spain, Switzerland, United Kingdom, and the United States of America.9

The OIE Terrestrial Animal Health Code describes five BSE risk categories for countries. In order of increasing incidence of BSE these categories are: BSE free, BSE provisionally free, minimal BSE risk, moderate BSE risk, high BSE risk. These classifications can be important in trade.

**Occurrence in cattle**

**Great Britain**

In Great Britain, the first known clinical case probably occurred in 1985. The annual incidence subsequently increased and the disease became a major epizootic in the late 1980s. The disease was declared notifiable, and a statutory ban on the feeding of ruminant-derived protein to ruminants was introduced in 1988. A more extensive ban on feeding any animal protein to any agricultural animal was later implemented to avoid feed cross-contamination. The annual incidence peaked in 1992 and has fallen every year since to produce a bell-shaped epidemic curve at approximately the year 2000, with some cases every year since. The reduction from the peak in 1992 is attributed to the 1988 ruminant-feed ban with the delay in response an effect of the incubation period of this disease. Britain has had the greatest number of affected cattle and provides the most information on the disease.

**Herd type**

The great proportion of cases have occurred in **dairy and dairy crossbred herds**, and by 2002 61.7% of dairy herds in Great Britain had experienced one or more cases.10 In contrast, 17.1% of **beef herds** had cases in the same time period. There has been no apparent breed predisposition. In both herd types, the risk for cases increased significantly with increasing herd size. A significant proportion of the cases in beef cattle herds have occurred in animals purchased into the herds from dairy herds. The reason for this difference in herd type is believed to be the greater use of concentrates in dairy cattle.

The disease has occurred in all regions of the country but was most prevalent in southwest England. Although the disease developed to an epizootic within the country, the disease does not occur as an epizootic within affected herds and most experience either single cases or a limited number of cases. The average **within-herd incidence** has remained below 2% since the disease was first described.

**Northern Ireland and Republic of Ireland**

In Northern Ireland the disease was recognized in 1998 and in the Republic of Ireland in 1999 but **epizootic disease** occurred Great Britain and Northern Ireland.10-12 The epidemiological features in both countries were similar to that in Great Britain, but the incidence has been lower. In Northern Ireland the incidence was approximately one tenth of that in Britain.11 The yearly incidence of the disease peaked in 1994 in Northern Ireland but jumped unexpectedly in the Republic of Ireland in 1996 to 1998 and has remained high since. The source of infection in both countries is believed to have been meat-and-bone meal imported from Great Britain. In the Republic of Ireland there has been geographic clustering with a higher incidence in two counties13 possibly associated with the location of feed suppliers.

**European continent and Iberian Peninsula**

On the European continent the disease was recognized in Switzerland in 1999 and shortly after on the Iberian peninsula in Portugal. Both countries showed a case incidence with evidence of an epidemic curve. However this was not mirrored in European Union (EU) member states in the continent, where only sporadic cases were reported in the 1990s, and it appears that the disease in this region was unrecognized, under-reported, and was more widespread than recorded.14-15 Apparently cattle with typical clinical manifestations and fallen stock with clinical signs that should have led to a suspicion of BSE were misdiagnosed or not reported.16

Switzerland established a surveillance system in 1999 testing fallen cattle, emergency slaughter and normal cattle using Prionics western blot rapid testing methods.17 This surveillance method was rapidly adopted EU member countries so that all but two had recorded cases by the end of 2001. In France, between the first notified case in the 1991 and the establishment of mandatory testing in 2000 there were 103 cases detected by passive surveillances but it is estimated that 301,200 cattle were infected with BSE during this period.18

---

**Fig. 23.1 Annual reports of incidence of BSE in the UK (1987-1998).**
Canada experienced a case of BSE in a cow imported from Great Britain in 1993 but the first case in an indigenous Canadian cow occurred in 2003 in Alberta. Trace back on 40 herds and slaughter of over 2000 suspects were all negative. The molecular profile of the BSE agent from this case was very similar to the UK BSE strains and had no relation to the agent associated with chronic wasting disease in deer and elk. In 2003 a Canadian cow that had been exported to the USA as a young cow developed complications at parturition, was shipped as a non-ambulatory cow, and was discovered as a BSE case under a routine monitoring program of downer cows. Canada had two more cases of BSE in 2005. The US had had a case in a native born cow in 2005. Trace back and slaughter study of birth contemporaries have proven negative for BSE. Affected animals in both countries were born before the ban on feeding MBM in 1997.

Age incidence
BSE, like scrapie, has a long incubation period, 2.5 to at least 8 years and possibly for the lifespan of cattle, and is a disease that affects mature animals. Epidemiological studies suggest that most affected cattle have been infected as calves. Risk is greatest in the first 6 months of life and between 6 and 24 months of age risk is related to feeding patterns of proprietary concentrates. Adult cattle are at low risk for infection.

The modal age at onset of clinical signs is between 4 and 5 years but there is a skewed distribution with the youngest age at onset recorded at 22 months and the oldest at 15 years. During the course of the outbreak in the UK there has been a change in the age distribution of cases in both Britain and Northern Ireland, consistent with a sudden decrease in exposure as a result of the bans on ruminant protein feeding. The clinical course is variable but the case fatality is 100%. There is a variation in risk associated with the calendar month of birth related to seasonal differences in calf management and exposure to ruminant protein in calf feeds.

Other species
Spongiform encephalopathies have been identified in seven species of ungulates in zoos or wildlife parks in Great Britain since the occurrence of the disease in cattle. These animals had been fed meat-and-bone meal but the apparently shorter incubation period suggests that they might be more susceptible to infection than cattle and there is evidence for horizontal transmission.

Feline spongiform encephalopathy (FSE) is also recorded in domestic cats in Great Britain since 1990 and in zoo felids. The zoo felids had been fed cattle carcasses unfit for human consumption, or the zoo had a history of BSE in exotic ruminants and fed culled carcasses to other zoo animals. Transmission studies in mice with the agents associated with these encephalopathies in zoo ungulates and felids suggest that they are the same strain as causes BSE. The initial concern that there would be an outbreak of FSE in domestic cats did not occur and only 89 cases were confirmed to the end on 2003.

Method of natural transmission
Ingestion of meat-and-bone meal
The initial epidemiological studies suggested that the disease in the UK was an extended common-source epidemic and the only common source identified in these initial studies was the feeding of proprietary concentrate feedstuffs. Epidemiological studies also suggested that presence of meat-and-bone meal in proprietary concentrates was the proxy for affected cattle to have been exposed to a scrapie-like agent, and this conclusion is supported by case-control studies examining feeding practices to calves that subsequently developed the disease. This hypothesis explains breed differences in incidence, as concentrates are not commonly fed to beef calves in the UK, and also can account for geographical differences in incidence. The oral route of challenge is known to be an inefficient route for the transmission of the agents associated with spongiform encephalopathies and this is believed the reason for the low within-herd incidence of the disease in the face of a common exposure.

Meat-and-bone meal is manufactured by the rendering industry from tissues discarded in slaughterhouses, and also from down and dead livestock. The outbreak of BSE in Britain was temporarily preceded by a change in the method of processing of meat-and-bone meal to a continuous process with a cessation of the use of hydrocarbon fat solvents. It is postulated that this change, coupled with the high sheep to cattle ratio in Great Britain, allowed the greater survival of a scrapie-like agent in scrapie-infected sheep carcasses processed to meat-and-bone meal to reach a level that was infective for cattle. An alternate hypothesis is that the agent came from existing, but low incidence and unrecognized, cases of BSE. The initial exposure occurred in 1981/82 and, subsequently, the agent recycled from infected cattle carcasses and offal used in the preparation of meat-and-bone meal.

Rendering procedures have subsequently been devised to minimize survival of the agent.

The marked fall in disease incidence following the introduction of the feed ban in 1987 in the UK substantiated the importance of ingestion of meat-and-bone meal as the major method of infection. Bans in Europe were largely introduced in 1990.

Born-after-the-ban
In the UK and in other countries a number of cattle that were born-after-the-ban (BAB, French acronym NAAB) have developed the disease. Most of these were born in the years immediately following the ban and their numbers have decreased in subsequent years but still continue at low levels. In the UK the clustering was related to areas with high concentrations of pigs and poultry and it is believed that there was cross-contamination of feedstuffs in feedmills. This is certainly possible with an infective dose of one gram less.

More recently there has been concern at cattle in the UK that have developed BSE but that were born after the implementation of the reinforced feed ban in 1996 (BARRs). To 2003 there have been approximately 100 cases. Again there is no evidence of maternal or lateral transmission and the inadvertent use of illegal feed material residual on farms is suspected.

Non-feedborne transmission
There is no epidemiological evidence for significant horizontal or vertical transmission of the disease in cattle although the studies suggest that minor horizontal transmission may occur to birth cohorts of calves that subsequently develop BSE. This type of transmission is of minor importance to the perpetuation of the disease in a country, but it may be of significance to human health and birth cohorts are included in trace backs of infection in the USA and Canada.

Vertical transmission
In the absence of other mechanisms of transmission, vertical transmission is not considered significant for the perpetuation of the disease in an epidemic form. There is an enhanced risk for the disease in calves born to infected cows, and this is higher in calves born after the onset of clinical disease in the cow. This may be the result of exposure, at birth, to high infectivity in birth products as there is no evidence for infection and transmission in embryo transplants. However, no detectable infectivity has been found in placentas from cows with the disease.
A very elegant experiment that examined the risk for transmission of BSE via embryo transfer and which used recipient cattle sourced from New Zealand and donor cows clinically affected with BSE, bred to bulls that did and did not have clinical BSE, concluded, after a 7-year observation period on the progeny, that embryos were unlikely to carry BSE.40

Risk for occurrence of disease in countries
Changes in the method of processing meat-and-bone meal have occurred in countries other than the UK and scrapie occurs in sheep in other countries. However, the major risk for the occurrence of the disease in other countries is the importation of latently infected cattle and/or the importation of infected meat-and-bone meal. This risk can be substantially avoided by prohibiting the feeding meat-and-bone meal to cattle.

An assessment in 1996 of risk for the occurrence of BSE in the United States concluded that the potential risk of an epizootic was small and that there are substantial differences in the strength of the risk factors between the USA and the UK.41 These result from differences in proportional numbers of sheep and cattle, differences in the nature of the beef and dairy industries, the type of animal used for beef production and the age at slaughter, differences in the prevalence of scrapie, differences in the rendering industry with a much lower proportion of rendered animal protein originating from sheep in the USA, and differences in the practice of feeding ruminant-derived protein in calf rations, which is uncommon in the USA.42,43 An analysis published in 2004 concluded the same.44

Thus the risk of an outbreak similar to that in the UK was considered negligible. However a case in a native cow in the US has occurred in 2005. This, and the recent cases in Canada suggests that infected meat-and-bone meal was imported to the North American continent at some time. The cases in both countries occurred in cattle that were born before the ban on feeding meat-and-bone meal imposed in both countries in 1997.

Countries with largely pastoral cattle are at low risk 45

The International Animal health code of the OIE describes five BSE risk categories for countries based on the importation of cattle from at-risk countries, the importation of potentially infected meat-and-bone meal, the consumption of meat-and-bone meal by cattle and other animals, animal feeding practices, livestock population structure, rendering practices and the potential for recycling of BSE. In order of increasing incidence of BSE these categories are: BSE free, BSE provisionally free, minimal BSE risk, moderate BSE risk, high BSE risk.46

Experimental reproduction
While studies on the transmissibility and experimental reproduction of BSE were established before the occurrence of human cases of BSE (vCJD) they have been critical in determining the risk of cattle products for human disease and the risk for disease in other species.

In cattle, disease has been experimentally reproduced by oral, and intracerebral inoculation with infected cattle brain homogenates.

Oral, intravenous and intracerebral inoculation of sheep with infected cattle brain homogenates also results in disease. Disease has also been reproduced in goats and mink by parenteral challenge. In pigs, disease has been produced by intracerebral challenge with infected brain homogenates but not oral challenge. It has not been produced by any route of challenge in poultry and is not produced by oral challenge in farmed deer.47

The disease can also be produced and passed in a variety of laboratory mice strains.

Some details of the results of the temporal infectivity of tissues produced in cattle by oral challenge with homogenates of infected brain tissue are given below under the heading pathogenesis.

In the initial oral challenge studies, cattle were challenged with a 100 g dose of brain homogenate that contained $10^{3.5}$ intracerebral/intraperitoneal LD50/g of BSE.48 There is currently a study in progress that examines the effect of dose on the incubation period of BSE and the distribution of infectivity. Dose rates of brain of 1 g have produced the disease and studies will continue with lower doses.

Infectivity of tissues
Brain, spinal cord and retina are tissues that are infective to cattle or laboratory animals from natural cases of BSE. The tissues that are infective to cattle or laboratory animals from experimentally infected cattle are brain, spinal cord, retina, distal ileum, bone marrow, trigeminal nerve and lingual lymph tissue.49-51

Other tissues including the major visceral organs, striated muscle and tissue common for human consumption were negative by mouse bioassay, indicating that no infectivity could be detected. These tissue are currently being re-examined for infectivity using the most sensitive assay known, intracerebral injection into the host species - in this case cattle. These studies are on-going but, at last report49 have only confirmed the results of the negative mouse bioassays. There is no evidence of infectivity in milk based on the fact that calves suckling cows with clinical BSE do not themselves develop BSE when mature and also on the lack of infectivity with intracerebral injection of mice.50,51

Economic importance
BSE is not of major economic significance to individual herds in countries in which it is endemic because of the low within-herd incidence. In most countries, compensation will cover cases detected by passive surveillance and, with active surveillance, most the costs if there is selective culling in affected and trace back herds.

However, it is arguable that this disease is the most economically devastating agricultural animal disease in the developed world.

The disease has been of major economic importance in the UK and is estimated to have cost £500 billion.52 This has been due to the national cost associated with detection and control procedures, the cost of compensation and disposal of affected animals. These costs, along with the cost of loss of export markets are very high.

Worldwide, the public has developed an extreme concern for the public health risk associated with BSE infection in cattle and consequently all countries have been mandated or encouraged to develop active surveillance programs. Not to do so runs the risk of loss of overseas markets and loss of home consumption of beef in favor of other meats.

Further, the detection of a single case of BSE by these active surveillance programs results in loss of export markets for the country and a severe fall in cattle prices for countries that rely on exports in their cattle industries.

BSE is also arguably the disease that has been used most to influence trade in live cattle and cattle products with no science-base or attention to the internationally adopted OIE Terrestrial Animal
Health Code. This largely because of the success of local political influence of ranches and farmers.

It is further arguable that the money spent, for reasons of public health, on this relatively minor zoonotic disease, by far outweighs its relative importance as a cause of human disease.

**Zoonotic implications**

Concerns that this disease could transmit to man were raised a very short time after its initial diagnosis. These unfortunately proved true in 1996 when a new form of CJD was reported. While, with the initial cases, there was reservation as to causality, studies showed the agent associated with this disease is similar to that associated with BSE and the feline spongiform encephalopathies and there is now no doubt that this is a form of BSE in man. It differs from CJD in that it affects young people with a mean age onset in the third decade of life. In humans there is evidence for genetic susceptibility and all cases have been homozgyous for methionine at codon 129. The disease has been termed variant CJD (vCJD).

The disease occurred in the UK despite the progressive bans on human consumption of beef products that contained infectivity that were implemented in 1998 and subsequently tightened further as new information on potential infectivity became available. It is possible that exposure of affected humans occurred in the early and mid 1980s, prior to the recognition of the disease. There was initially extreme concern that there would be a very large outbreak in humans. However, this has not occurred. The total number of deaths form vCJD in the UK has reached 150. The peak number of deaths occurred in the year 2000 and the outbreak appears to have reached a plateau and is possibly in decline although the nature of the outbreak will dependant on the range of incubation periods in humans.

Also, cases of vCJD are more recently being reported from the European continent and the Iberian peninsula.

While there is no evidence of direct transmission to humans, veterinarians and animal handlers should take appropriate precautions when handling nervous system tissues of infected animals.

**PATHOGENESIS**

Information on the pathogenesis and development of BSE in cattle derives almost entirely from studies published from Britain in the 1990s that studied the spatial and temporal development of infectivity and pathological change in cattle after oral challenge with a 100 g dose of BSE-affected brain homogenate sourced from naturally clinically affected cattle. The experimental cattle were killed sequentially following challenge and infectivity in tissues subsequently determined by initially by infectivity assays by intracerebral and intraperitoneal injection into panels of inbred mice, and subsequently by infectivity studies by intracerebral challenge of cattle to exclude any species barrier effects.

Following oral challenge of calves, infectivity was initially detectable in the distal ileum, in the Peyer’s patches, but no infection is demonstrable in other lymphoreticular organs. Infectivity was demonstrable in the cervical and thoracic dorsal root ganglia at 32–40 months after infection and in the trigeminal ganglion at 36–38 months. Traces of infectivity were shown in sternal bone marrow in cattle killed 38 months post exposure. The earliest presence of abnormal PrP and infectivity in the CNS occurred 32 months post-exposure, prior to any typical diagnostic histopathological changes in the brain. The onset of clinical signs and pathological change in the brain occurs at approximately the same time.

**CLINICAL FINDINGS**

The disease is insidious in onset and the clinical course progresses over several weeks, varying from 1 to 6 months in duration. There is a constellation of clinical signs with alterations in behavior, temperament, posture, sensorium and movement, but the clinical signs are variable from day to day although they are progressive over time. Cattle that show behavioral, sensory and locomotor abnormality together are highly suspect for BSE. The predominant neurological signs are apprehensive behavior, hyperesthesia and ataxia, and a high proportion of cases lose body condition and have a diminishing milk yield during the clinical course of the disease.

- **Long incubation period (5 years)**

- **Oral infection**

- **Infection of Peyer’s patches, to brainstem via vagus nerve**

- **Accumulation of abnormal prions destroys brain slowly**

**Clinical signs in BSE**

- Change in temperament and behavior
  - apprehension, excitable, unusual kicking, head tossing when haltered, separation from group
- Change in posture and movement
  - abnormal posture and ataxia
- Fall in milk production
- No ante-mortem test available

**Behavioral changes** are gradual in onset and include changes, such as a reluctance to pass through the milking shed or to leave a vehicle or a pen, a change in milking order and a reluctance to pass through passageways. Affected cattle are disoriented and may stare, presumably at imaginary objects, for long periods. There is hyperesthesia to sound and touch, with twitching of the ears or more general muscle fasciculation and tremors. Many throw their head sideways and show head shaking when the head or neck is touched.

Other changes in temperament include the avoidance of other cows in loose housing, but antagonistic behavior to herdmates and humans when in confined situations. Affected animals may kick during milking and show resistance to handling. Some cows show excessive grooming and licking, and may show the equivalent of the scratch reflex.

**Bradykardia**, associated with increased vagal tone and not occurring due to decreased food intake is reported and may persist despite the cow’s nervousness during clinical examination.

Relatively early in the course of the disease there is **hindlimb ataxia** with a shortened stride, swaying gait, and difficulty in negotiating turns.

This should be especially examined as animals exit transport vehicles or are trotted through an area. Knuckling, stumbling and falling, with subsequent difficulty in rising is common in the later stages of the disease. Cows show **progressive weakness**, with ataxia and weight loss, and prior to the common recognition of the disease, they were sent to slaughter because of locomotor disabilities or changes in temperament.

It has been recommended that the animals reaction to sudden noise, sudden light, sudden movement and sudden touch be used as a test. Sudden noise is tested by clanging two metal objects together out of sight of the animal – the bang test; sudden light by testing with a camera flash – the flash test; sudden movement tested by waving a clipboard towards the cow from a short distance – the clipboard test and sudden touch by touching the animal on the hind limbs a soft stick – stick test.

Abnormal reactions to these tests include being startled, head tossing, salivation, snorting, running away or panicky circling and kicking out on touch. These tests have been found positive in BSE suspects that had a history of behavioral change but did not show abnormalities of gait.

Cattle with BSE do not always show neurological signs in the initial stages of the disease and animals with BSE may be sent to slaughter for poor production.
prior to the onset of clinical nervous signs.17

**Clinical signs and passive surveillance**

There is yet no preclinical test for BSE and clinical recognition of BSE is the major component of passive surveillance. At the peak of the outbreak in Britain, BSE was confirmed in 85% of cases picked by passive surveillance. This percentage fell to 56% later in the outbreak. Farmers were fully compensated at notification and well informed and so were probably motivated to contact their veterinarian. Veterinarians were also very aware of the clinical presentation of BSE and observed at livestock markets and while TB testing and at abattoirs.35 Relatively high success rates were also found in Switzerland where approximately 59% of animals notified with BSE were confirmed.60,61 However, in other countries, passive surveillance was an utter failure.15,62

While an aid to surveillance of a disease, passive surveillance of BSE based on clinical signs is an insensitive method of disease detection and targeting surveillance of emergency slaughtered cattle and fallen stock is 40 times more likely to detect case of BSE than notification on the basis of clinical signs. One study found that the odds of finding a BSE case was 49 times higher in the fallen stock and 58 times higher in emergency slaughtered cattle greater than 24 months of age when compared with passive surveillance of clinical disease.91

**CLINICAL PATHOLOGY**

There is no specific test for the ante-mortem diagnosis of this disease. Apolipoprotein E and two unidentified proteins are present in the cerebrospinal fluid from clinical cases but not normal cattle, and the presence of a 30 kDa, 14–3–3 protein in cerebrospinal fluid in affected cows is reported, but there is no information of specificity.63,64 Electroencephalographic and evoked potential diagnostic methods have been proposed as ante-mortem diagnostic test methods but require further evaluation and would seem impractical.

**NECROPSY FINDINGS**

There are no abnormalities in gross pathology, and diagnosis is dependent upon histological findings.66 Major changes are in the brain stem, and the pathognomonic lesion is a bilaterally symmetric intracytoplasmic vacuolation of neurons and gray matter neuropil. The occurrence of vacuolation in the solitary tract and the spinal tract of the trigeminal nerve in the medulla oblongata is the basis of statutory diagnosis of the disease in Great Britain. In Great Britain, statutory diagnosis is achieved by an examination of a single brain stem section obtained via the foramen magnum and obviating the need of extracting the brain with the associated risk of aerosol production.28

Histological findings are diagnostic in many cases but can be supplemented with the immunodetection of PrPSc in brain tissue by in situ immunohistochemistry and Western immunoblots.

There are a number of validated rapid tests for BSE.67 Recently it has been established that the sensitivities of detection of BSE-specific PrP by immunohistochemistry and the detection of infectivity by mouse inoculation are equivalent and similar to the sensitivity of the rapid method (BSE Bio-Rad) for detection of PrPSc.47,68

Scrapie-associated fibrils can be visualized by electron microscopy. Government regulatory agencies are usually responsible for the confirmation of this diagnosis and typically distribute specific protocols regarding the collection of samples and disposal of carcasses from suspect animals.

**Samples for confirmation of diagnosis**

- **Histology** – formalin-fixed brain, including midbrain and entire medulla oblongata (LM).

Note the zoonotic potential of this disease when handling carcass and submitting specimens.

**Differential Diagnosis**

The disease should be considered in the differential diagnosis of any progressive neurological disease in cattle. Primary differentials on clinical signs include:

- Hypomagnesemia
- Nervous acetoneemia
- Rabies
- Lead poisoning
- Listeriosis
- Polioencephalomalacia
- Tremorgenic toxins.

**Bovine amyloidotic spongiform encephalopathy**. In both Italy and France a form of spongiform encephalopathy different from BSE has been detected in brains collected as part of the active surveillance program in those countries. The cases were in older cattle and pathologically characterized by the presence of PrP-immunopositive amyloid plaques, as opposed to the lack of amyloid deposition in typical BSE cases, and by less involvement of the brainstem. There was some similarity to CJD in humans. There is no information on clinical presentation.69 Other atypical forms have been reported in Belgium, and Japan.70

**TREATMENT AND CONTROL**

There is no treatment for the disease.

**Detection of BSE in surveillance and control programs**

Passive surveillance has been used in many countries. Suspect disease is notifiable with compulsory slaughter and compensation and disposal of the carcass by incineration. The limitations of passive surveillance are described above in the section on clinical findings and, in most countries, passive surveillance has been replaced with some form of active surveillance.

Commonly, active surveillance is directed at a targeted proportion of culled animals, animal manifesting neurological disease, rabies-suspects negative for rabies, and a proportion of cattle, or all cattle, over 24 to 30 months (depending on country) that are presented for slaughter for human consumption. In slaughter cattle, the sampling frame is set to detect BSE at a prevalence rate of one mature animal in a million mature animals. The ability to conduct active surveillance, particularly on slaughter cattle, has been allowed by the development of rapid tests that can be conducted and read while the carcass is being held so that positive test cattle are not released for human consumption. Positive rapid tests need to be confirmed by histology and immunohistochemistry.65,71

In the US, following the case of BSE in an imported cow, the USDA implemented an intensive national testing program for BSE that concentrated on a targeted high-risk population. The purpose is to help define if BSE is in the US and, if so, at what level. The intention is to sample as many cattle over a 12 to 18 month period as possible with the goal of examining 268 500 cattle which would allow a detection rate of 1 in 10 million with a 99% confidence level.72 The cattle will be over 30 months-of-age and include nonambulatory cattle, cattle that are too weak to walk, cattle that are moribund, cattle with neurological signs, rabies suspects that are negative and dead cattle. At the time of writing (2005) the survey is in currently in progress but has identified one native born BSE cow.

**Control of BSE in cattle**

Control programs have the following assumptions:

- Infection and disease in cattle is introduced through feeding contaminated feed containing infected meat-and-bone meal or greaves
- The source of infection to cattle can be eliminated by effective prohibition on feeding infected feed
- There is no significant horizontal or vertical transmission

Based on this, most countries have established a ban on the feeding of ruminant protein to ruminants. This was done in the 1987 in the UK, the mid 1990s in most European countries and in 1997

BSE AND SHEEP

There is considerable speculation and concern that the agent of BSE could have become established in small ruminants. BSE can be readily experimentally transmitted to sheep and goats and produces clinical signs and lesions similar to scrapie. There is further concern following a recent report of the transmission of the agent from challenged ewes to their lambs.1 Further, the risk to human health from the ingestion of meat from sheep may be even greater than that from cattle because of the widespread distribution of the BSE agent in the lymphoid tissue of infected sheep.

In the UK and Europe concentrations are commonly fed to meat producing breeds of sheep in late pregnancy and early lactation and less commonly to their lambs. They are also fed to milk-producing sheep breeds and to lactating goats. Concentrates fed during the 1980s and 1990s could have contained infected meat-and-bone meal and this risk would have lasted until the total ban on feeding MBM to all farm animals in 1996 in the UK and 2001 in Europe.

The inclusion of meat-and-bone meal in concentrate rations for small ruminants was less than that for cattle and the proportion of concentrate ration fed was also lower. This, coupled with the fact that prion diseases require a larger infective dose to produce disease in a cross-species to that required to produce the disease in the same species, the species barrier effect, may have resulted in an infective dose to sheep was too low to establish infection.2,3
The possibility that BSE did establish in sheep during the BSE epidemic in Britain is not supported by a study that examined the incidence and new infection rates of scrapie flocks in Britain covering the period from 1962 to 1998. This study found no evidence of a change in scrapie occurrence prior to, during, or following the period from 1985 to 1998. There is no information on other routes of transmission and if they exist.

PATHOGENESIS
Following challenge of sheep with BSE, infectivity has been found in intestinal Peyer's patches as early as 5 months post-infection and in enteric nerves and spinal cord after 10 months with widespread dissemination throughout the lymphoreticular system and peripheral nervous system by 21 months.

CLINICAL SIGNS
The clinical signs reported in affected experimental animals are not well described in many of the experimental challenge studies but have varied in different studies. In one study, sheep and goats showed sudden onset of ataxia which progressed rapidly to recumbency. There was little evidence of pruritus and the clinical course was very short, lasting between 1 and 5 days in the majority of animals with one goat showing progressive weight loss over 3 weeks before it was culled. Genotype had no influence on the duration of the clinical course. In another study in sheep only, the clinical course was approximately 3 months and affected sheep showed pruritus with feeding loss and ataxia and behavioral changes. Ataxia, weight loss, pruritus were considered constant in another.

In an experiment designed to test specifically if clinical signs could be used for differentiation between scrapie and BSE, two different groups of sheep were inoculated with each agent. The duration of clinical signs varied quite markedly with a characteristic range of incubation periods. However this is not true with scrapie and BSE could easily result in naturally occurring cases of BSE in sheep being misdiagnosed as scrapie.

DIAGNOSIS
The diagnosis of BSE in clinically affected cattle can be achieved with several techniques, including the analysis of symptoms, histopathology and the detection of the disease-associated form of the prion protein, by immunocytochemistry, western blot or ELISA. The profiling of vacuoles in affected host had shown a remarkable uniformity over the year and from different geographic regions. However this is not true with scrapie and the variation in the host brain with scrapie would not allow differentiation from BSE on histological findings. The diagnosis of BSE in sheep presents problems and the similarity of the clinical signs and pathology between scrapie and BSE could easily result in naturally occurring cases of BSE in sheep being misdiagnosed as scrapie.

Strain typing
The 'gold-standard' technique for the diagnosis of TSE agents is the passage of tissue in panels of inbred mice, a technique known as 'strain typing'. Until recently this was the only way to differentiate the two diseases. BSE presents with a characteristic range of incubation periods and a pattern of distribution and relative severity of changes in the brain of the different mouse strains - the lesion profile - which is distinct from all scrapie strains tested to date. However, this method of diagnosis is both expensive and time-consuming.

There has been a wide search for a differential test system in including prion protein profiling, studies in glycosylation and glycoform ratios and other molecular and biochemical studies that are detailed elsewhere. A recent promising set of studies suggests that the site of truncation of disease-associated PrP in peripheral lymphoid tissue in ARR/ARR genotype sheep and lack of infectivity and there appears to be an inverse relation between this disposition and the incubation period. Route of inoculation influences the relative intensity of disposition in tonsil, spleen and mesenteric lymph node.

Following experimental infection of sheep with BSE, disease-associated PrP can be detected in tonsils biopsies 11 to 20 months after challenge but, in contrast to scrapie, disease-associated PrP is not detected in biopsies of lymphoid tissue from the third eyelid.

DISPOSITION OF DISEASE-ASSOCIATED PPr
Genotype and route of inoculation influence the disposition of disease-associated PrP in lymphoreticular system of infected cattle brain and subsequently mated. Twenty-four developed clinical disease between 655 and 1065 days post-inoculation and two lambs, born before their dams had clinical disease, also subsequently developed clinical disease. This study indicated that the agent of BSE can transmit either in utero or perinatally in sheep. There is no information on other routes of transmission and if they exist.
rise to different immunohistochemical patterns and this is supported by western blot studies. Unlike scrapie, the intracellular truncation site of ovine BSE PrP is influenced by the cell type in which it accumulates giving distinct patterns of immunolabeling with different PrP antibodies. Epitope labeling shows that the shortest fragment of disease-associated PrP occurs in tangible body macrophages following glial cells and neurons. It appears that this difference in truncation of PrP in experimentally infected BSE sheep is not influenced by route of inoculation or by genotype or by sheep breed, and it is proposed that truncation patterns, as detected by immunoblotting and immunohistochemistry, can be used in surveys for BSE in sheep.

CONTROL

If BSE is or does establish in small ruminants in a country there is a significant concern for human health. The distribution of BSE infection in the carcasses of cattle is limited and can be removed by the ban of the use of specified risk materials (largely brain spinal cord and offals). In contrast, the distribution of the BSE agent in infected sheep is widespread and it would be virtually impossible to remove this by trimming or selective organ removal from a carcass for human consumption. Also lymphocytes in milk could be infected.

In the UK, a worst case scenario, published in 2001 in a contingency plan to address BSE in sheep, threatened the national herd with slaughter, largely on the ground that an epidemic of BSE in sheep could be harder to contain than the case for BSE in cattle, and that lamb could present a greater risk to consumers than beef. A more recent UK contingency plan would allow PrP genotype ARR homozygous sheep and ARR heterozygous sheep for human consumption. This plan is the same as the EU, except that there are differences in the maximum age allowed at slaughter between the UK and the EU recommendations.

The risk for BSE in sheep was a major incentive for the development of national breeding programs for the control of scrapie, and possible BSE, including the National Scrapie Plan in the UK, launched in 2001, and the National Scarpie Eradication Program in the US. The purpose in these breeding programs is to select against highly susceptible genotypes and select for the highly resistant genotype.

CHRONIC WASTING DISEASE

Chronic wasting disease (CWD) has recently emerged, or been recognized, in the USA as a transmissible spongiform encephalopathy of captive and free-ranging cervids. The ability of this infection to transmit laterally between cervids, coupled with the longevity of the agent in the environment and the common grazing land of infected cervids and cattle and sheep have resulted in concern that CWD in cervids might be a risk to livestock, and subsequently to humans, similar to bovine spongiform encephalopathy. There has also been concern that it might be transmitted directly from infected cervids to hunters dressing carcasses or consuming deer meat. To date there is no evidence for either of these risks.

The known natural hosts for CWD are mule deer (Odocoileus hemionus), white-tailed deer (Odocoileus virginianus) and Rocky Mountain elk (Cervus elaphus nelsoni). CWD was originally recorded in the late 1960s as a chronic wasting syndrome of unknown etiology in captive mule deer in research facilities in Colorado and Wyoming. It was subsequently established that the disease was a transmissible spongiform encephalopathy and CWD has subsequently been found affecting cervids in captivity in several states in the USA and also in the provinces of Saskatchewan and Alberta in Canada. The occurrence in captive and farmed cervids in these different geographical areas is likely the result of transfer of animals between them, and the disease has recently been reported in Korea in cervids imported from North America.

The disease has a focus, and may have originated, in free ranging deer and elk in north-central Colorado and southeastern Wyoming, however, in recent years it has been detected in free ranging cervids east of the Mississipi and in a much broader area of North America. It is not certain if this is due to spread or because of improved surveillance. Based on comparisons of the central nervous system lesions and the glycoform patterns, the CWD agent is the same in captive and free-ranging deer.

There is strong evidence from outbreaks in captive deer that lateral transmission is of major importance in the transmission of CWD. The agent accumulates in gut-associated lymphoid tissues early in the infection and saliva and feces are the likely sources of infection with contamination of the environment.

The disease can be transmitted experimentally between cervids and there is evidence for genetic susceptibility. The prion associated with CWD is not the same as that associated with BSE. In a recent study, it was shown that infection, with amplification of prion protein in brain tissue, can be transmitted to cattle by intracerebral inoculation of CWD-infected deer brain. Six years following challenge less than 50% of the challenged cattle showed amplification of the infection and none had histological evidence of spongiform encephalopathy. It was concluded that if infection via the oral route did occur in cattle it would be unlikely that it would result in amplification of the abnormal prion within the lifespan of cattle.

Clinically the disease in cervids is manifest initially by changes in behavior, not commonly observed in free-ranging cervids, with the major manifestation being a marked fall in body condition. In the terminal stages there may be ataxia and excitability. The clinical course varies from a few days to a year but averages 4 months. Diagnosis is by histological examination of the brain or more commonly by the demonstration of PrPSc in brain tissue by immunohistochemistry.

Diseases associated with Rickettsiales

**Anaplasmosis**

**Etiology** Anaplasma marginale in cattle and wild ruminants, and *A. ovis* in sheep and goats. *A. centrale* causes mild anaplasmosis in cattle

**Epidemiology** Common in tropical and sub-tropical regions; sporadic in temperate regions. Carrier animals are the source of infection. Disease transmitted by ticks, mechanically by tabanid vectors, iatrogenically, and transfusionally. Disease can be endemic in tick areas or sporadic in interface regions between endemic and free areas.

**Clinical findings** In cattle death or severe debility, emaciation, anemia and jaundice are the major clinical signs. The disease is usually subclinical in sheep and goats.

**Clinical pathology** Anemia, demonstration of organism in red cells by microscopy, fluorescent stains or PCR, serology

**Necropsy findings** Anemia and attendant findings. Demonstration of organism

**Diagnostic confirmation** Detection of the organism in blood smears, positive serology, PCR, and in some circumstances positive transmission tests. The sensitivity, in a group of animals, can be increased by using parallel blood smears and serological tests.

**Treatment** Clinical cases treated with tetracycline or imidocarb. Blood transfusion. Carrier state cannot be eliminated by treatment with tetracycline.

**Control** Tetracycline provides temporary or prolonged protection in face of an outbreak. Vaccination with killed *A. marginale* vaccine or live *A. centrale* vaccine used in endemic areas as 6 weekly dipping in acaricides. In non-endemic areas, serological identification of carriers and culling or treatment of reactors. Prevention of iatrogenic transmission.

**Anaplasma** of which *A. marginale* is the type species, now also includes *A. bovis, A. platys*, and *A. phagocytophilum*, which were previously known as *Ehrlichia bovis, E. platys*, and *E. phagocytophilum*.1

*Anaplasma marginale* is the causative agent of anaplasmosis in cattle and wild ruminants, and *A. ovis* in sheep and goats. *A. centrale* is closely related to *A. marginale* and causes mild anaplasmosis in cattle. It was originally isolated in Africa but has been introduced as an immunizing agent in Australia, South America and Asia. There are antigenic variants among isolates of *A. marginale*, the six major surface protein antigens being antigenically polymorphic.1,2

**EPIDEMIOLOGY**

**Geographic occurrence** Anaplasmosis in cattle is common on all six continents, being present in South Africa, Australia, Asia, the former USSR, South America and the United States. It is transmitted by a diverse group of biological and mechanical vectors. Infection in cattle is endemic in tropical and subtropical areas that support large populations of these vectors. Infection occurs more sporadically in temperate climate areas.

In the United States, and in other countries, the disease has occurred beyond the boundaries of tick-infested areas and the area distribution in Europe has been advancing northward in recent years with sporadic cases in France, Switzerland, the Netherlands, Hungary, and Austria.3 Anaplasmosis of sheep and goats has a distribution similar to that of cattle.

In the USA anaplasmosis is enzootic throughout the southern Atlantic states, the Gulf Coast states and many of the midwestern and western states.4 Disease occurs sporadically in the northern states and Canada. In Australia infection is closely related to the distribution of *Boophilus microplus*, which is restricted to the northern areas. Seropositivity is negligible in cattle south of the tick line but above the tick line increases from south to north. Differences in enzootic and epizootic areas in South America and South Africa are also largely related to tick distribution and climate.

In most countries there is wide geographical variation in seroprevalence and this variability contributes to the development of geographically stable or unstable enzootic regions.

There is concern, and some evidence, that the global warming trend will expand the boundaries and movement of host ticks.1

**Host occurrence** Cattle are susceptible to *A. marginale* and *A. centrale* and sheep to *A. ovis*. *A. marginale* will establish in sheep by experimental infection but *A. ovis* will not infect cattle.5 A variety of species of wild ruminants in both North America and Africa can be infected and may have significance as reservoirs for *A. marginale*.6,7 In the United States the black-tail deer (*Odocoileus hemionus columbianus*) in the West Coast region is believed a reservoir and a number of species of antelope play a similar role in South Africa. Bighorn sheep (*Ovis canadensis*) may be a reservoir for *A. ovis* in the western United States.8

The prevalence of infection in cattle in endemic areas is very high with seropositivity rates exceeding 60% and often approaching 90%. Seropositivity is much lower in regions that interface between endemic and non-endemic regions.9

**Source and methods of transmission** The source of infection is always the blood of an infected animal. Recovery from acute infection results in persistent infection characterized by repetitive cycles of rickettsemia. Persistent carriers are the reservoir for herd infection. The level of parasitemia is often too low for detection by microscopy but can be detected by nucleic acid probe analysis.10 Transmission is biologically by ticks but can also occur transplacentally and can also be effected mechanically by biting flies or blood-contaminated fomites.

Hematophagous insect transmission Spread from animal to animal occurs chiefly by insect vectors. A variety of arthropods...
may act as vectors but significant natural vectors are ticks in the family Ixodidae and flies in the family Tabanidae. Of the ticks, the one-host Boophilus spp. are of major importance in tropical and subtropical regions and the three-host Dermacentor spp. of major importance in the western US.

The organism undergoes a complex developmental cycle in the gut cells of ticks and the final infective stage is present in the salivary gland. Trans-stadial transmission of the organism occurs in ticks but there is little evidence for transovarial transmission. Intra-stadial transmission is significant with some species and transmission occurs as the ticks move from one host to another while they are engorging, including from cow to calf. Male D. andersoni can act as effective vectors in this manner for at least 120 days.

There appears to be no developmental sequence of Anaplasma spp. in flying insects. Tabanids are efficient mechanical vectors and can transmit infection for 2 hours after feeding. Over 20 species of tick have been incriminated as vectors world-wide. In Australia the ticks Boophilus microplus and Rhipicephalus sanguineus are the vectors and in South Africa it is B. microplus, B. decoloratus, and Rhipicephalus simus. In the United States Boophilus annulatus, Dermacentor andersoni, D. variabilis, A. persicus and biting flies of tabanid species and eye gnats (Hippelates pusio) also act as vectors. The male ticks of Dermacentor albipictus (the winter tick) and D. occidentalis (the Pacific Coast tick) parasitize both deer and cattle and have been suspected as vectors.

Iatrogenic transmission

Anaplasmosis may also be spread mechanically by infected hypodermic needles, by castrating, spaying and dehorning instruments, and by blood transfusions and embryo transplants. The ease with which the infection is spread mechanically may vary with the virulence of the protozoan strain and this method of spread may be more important in some countries than others. Anaplasmosis may also be spread when cattle, used as donors of infected blood for immunization against babesiosis, are infected with A. marginale, the reaction occurring some 3 weeks later than that due to the babesia.

Transplacental transmission

Intra-uterine infection also occurs in cattle but much less frequently in field cases than in experimental ones. Abortion or neonatal infection may result. In sheep intra-uterine infection appears to occur with ease in experimental cases provided the ewe is exposed during the latter two-thirds of pregnancy.

Animal and environmental risk factors

Breed

Bos indicus, Bos taurus and their crosses have equal susceptibility to infection and show the same age susceptibility, but under field conditions Bos indicus are not as commonly affected, probably because of their relative resistance to heavy tick infestation. However, the effects of the disease on body weight and clinicopathological parameters are the same for the two races of cattle. Breeds with black or red coat color have a higher risk of infection than those with white coats in regions where biting flies are the insect vector. Dairy breeds may be at greater risk for iatrogenic transmission.

Nutritional status

Clinical disease is less severe in cattle on a low plane of nutrition. Exposure of infected, clinically normal animals to devitalizing environmental influences, particularly shortage of feed, and the presence of other diseases, may result in the development of acute anaplasmosis. For example, cattle introduced into feedlots are highly susceptible and outbreaks among them are not uncommon 2-3 weeks after entry.

Season

In temperate climates a seasonal occurrence of disease occurs in association with seasonal occurrence of the insect vectors. Winter outbreaks are likely associated with iatrogenic transmission or possibly the winter tick, D. albipictus.

Age at infection

All cattle are susceptible to infection but age at infection is a major determinant of the severity of clinical disease. Young calves are less susceptible to infection with A. marginale than older cattle and, when infected, are less susceptible to clinical disease. The reason for this is not understood but splenectomized calves are fully susceptible to infection, which may be more severe than in the adult. Infection between six months and three years of age has increasing risk of clinical illness and animals infected after 3 years of age are commonly affected by a peracute fatal form of the disease. The age-specific incidence of clinical disease recorded in an outbreak in the USA showed 81% of cases in cattle aged between 2-4 years with 94% of cases in cattle 3 years of age or older.

Geographic region

Clinical disease is rare in enzootic areas because the infection pressure is high and cattle are infected at an age when they are age-resistant to clinical disease. The average age at which calves in enzootic areas become infected is 11 (4-24) weeks and the clinical and hematological changes in them are mild and brief. Animals in an infected environment which have become seronegative for whatever reason are fully susceptible to infection. Clinical disease occurs where there is introduction of susceptible animals into endemic areas or the expansion of the vector population into previously free areas or into the interface between endemic and non-endemic regions.

Case fatality rates are usually high in outbreaks but the mortality rate varies widely depending on susceptibility, and may be 50% or more in cattle introduced to enzootic areas. Case fatality rates of 29-49% are recorded in outbreaks in the USA; recovered animals are emaciated and there is a prolonged convalescence.

Pathogen risk factors

Phylogenetic analysis of A. marginale geographic isolates support the existence of clades. Australian isolates do not appear to differ significantly in antigenicity or virulence. In contrast in other countries there can be significant differences between isolates in antigenic composition, the protection afforded against heterologous challenge and virulence.

Recent research has demonstrated that the phenomenon of infection exclusion occurs with A. marginale. Infection of tick cells and bovine erythrocytes with one genotype of Anaplasma marginale excluded infection with other genotypes and in herds of cattle from endemic areas where many genotypes were detected only one genotype was found per animal. Further cattle inoculated with two A. marginale isolates became infected with only one isolate.

Economic importance

Costs are from death and abortion in clinical cases, loss of production in sick and recovered animals, and costs associated with preventive measures such as tick control. There have been few recent estimates of cost, the most recent estimates in 1977 and were of a cost of $875 millions in Latin American nations.

In developed countries with the disease exports of cattle to countries that do not have it are constrained. A major cost in developing countries is the constraint to efficient production and the limit to the introduction of susceptible cattle breeds with superior genetics.

PATHOGENESIS

Anaplasma are obligate intra-erythrocytic bacteria. They infect mature erythrocytes by an endocytic process and reproduction occurs by binary fission to produce 2-8 infective initial bodies which leave by exocytosis to infect other erythrocytes. The number of infected erythrocytes doubles every 24-48 hours and the infection becomes patent 2-6 weeks after infection, the time influenced by the initial challenge dose. Depending upon the strain and
the susceptibility of the host, from 10–90% of erythrocytes may be parasitized in the acute stage of the infection. At least 15% have to be parasitized before there is clinical disease. Parasitized erythrocytes are removed by phagocytosis in the reticular endothelial system, with release of acute-phase inflammatory reactants and the consequent development of fever. Continued erythrocyte destruction occurs resulting in the development of mild to severe anemia and icterus without hemoglobinemia and hemoglobinuria. Anaplasmosis is primarily an anemia, the degree of anemia varying with the proportion of erythrocytes which are parasitized. The first appearance of the protozoa in the blood coincides with a fall in the hematocrit and erythrocyte levels, the appearance of immature erythrocytes in blood smears and the development of fever. Acutely affected animals may die shortly after this phase is reached. The appearance of anti-erythrocyte antibodies late in the acute stage may exacerbate the anemia.  

If the animal recovers from the initial acute attack, periodic attacks of parasitic invasion of mature erythrocytes occur regularly, but with diminishing intensity. The degree of anemia varies widely in young cattle up to 3 years of age but is always severe in adults and in splenectomized animals. Cattle that survive the disease become carriers and serve as reservoirs of *A. marginale* because they provide a source of infective blood for both mechanical and biological transmission by ticks. They have lifelong immunity and are resistant to clinical disease on challenge exposure.

Carrier animals have cycles of parasitemia, possibly associated with the development of new antigenic variants to allow new cycles of invasion and multiplication. These occur at approximate 5-week intervals during which the new variants replicate and are then controlled by a variant-specific immune response.

**CLINICAL FINDINGS**

**Cattle**

In cattle, the incubation period varies with the challenge dose but is generally about 3–4 weeks with tick-borne infection and 2–5 weeks with the inoculation of blood. In most cases the disease is subacute, especially in young animals. Rectal temperature rises rather slowly and rarely to above 40.5°C (105°F). It may remain elevated or fluctuate with irregular periods of fever and normal temperature alternating for several days to 2 weeks. Anorexia is seldom complete. Death can occur at this stage but many survive in an emaciated condition, and their fertility is impaired. The mucous membranes are jaundiced and show marked pallor, particularly after the acute stage is passed, but there is no hemoglobinuria.

Peracute cases, with a sudden onset of high fever, anemia, icterus, severe dyspnea and death, often within 24 hours, are not uncommon in adult dairy cows. Affected animals are often hyperexcitable and tend to attack attendants just before death. Pregnant cows frequently abort. In convalescent bulls there may be depressed testicular function for several months.

**Sheep and goats**

In sheep and goats, infection is usually subclinical but in some cases, particularly in goats, a severe anemia may occur and a clinical picture similar to that found in cattle may be seen. Severe reactions of this type in goats are most frequent when the animals are suffering from concurrent disease. Goats may show hyperexcitability and may bite at inanimate objects. The experimental disease in lambs includes fever, constipation or diarrhea, pale, icteric conjunctivae and severe anemia 15–20 days after inoculation. The anemia is not completely resolved in 3–4 months.

**CLINICAL PATHOLOGY**

**Hematology**

Erythrocyte destruction may be so severe that the erythrocyte count is reduced to 1.5 million/μL. Immature red cells are common at this stage and their presence is considered to be a favorable sign. The small dot-like protozoa are discernible at the periphery of up to 10% of the red cells in subacute cases, but in peracute cases more than 50% of the cells may be parasitized. *A. ovis* are usually situated at the periphery of erythrocytes but as many as 40% of infected cells may show submarginal protozoa. Diff-Quik staining of blood smears is as accurate as Giemsa in the detection of *A. marginale* and can be completed in 15 seconds as compared to nearly an hour for Giemsa. There are no diagnostic clinical chemistry findings.

**Serology**

The complement fixation test is the standard test for the detection of carrier animals. It is satisfactory for use in cattle, goats and sheep but the antibody titer is highest during the active phase of the disease and sufficiently low in carrier animals to give a proportion of false negative results. False positive reactions can occur because of erythrocyte contamination of the *A. marginale* antigen and the presence of antibodies to erythrocytes in some cattle sera. A rapid card agglutination test, which tests serum or plasma for antibodies against *A. marginale*, is cheap and quick, and sufficiently accurate to be used as a herd test. Currently, in most countries, the card agglutination and complement fixation tests are routinely available.

There are a number of other tests that have been developed. A capillary tube agglutination test of comparable efficiency is available, is more economical and faster than the CF test and is particularly suited to testing in extensive field situations. An indirect fluorescent antibody test is also accurate and has a particularly suitability for testing blood which has been dried onto paper for passage through the mails. It is also an accurate test for selecting recently affected animals. A dot-ELISA with high sensitivity and specificity, and has been developed that detects antibody to a major surface protein that is conserved among anaplasma species; this test can be used to detect cattle persistently infected for as long as six years. Vaccinated animals may react to all of the serological tests for periods of over one year.

**Other methods**

- **Nucleic probe analysis** can be used to detect low levels of parasitemia.
- **Transmission** to splenectomized animals has been used to detect carriers but is expensive and is now replaced by PCR in countries where this technology is available.

**NECROPSY FINDINGS**

The most obvious findings are emaciation, pallor of the tissues, and thin, watery blood. There is mild jaundice and the liver is enlarged and orange. The kidneys are congested and there may be myocardial hemorrhages. The spleen is enlarged with a soft pulp. The bone marrow cavity may be reddened by increased hematopoietic tissue in acute cases but there may be serious atrophy of marrow fat in chronic cases. Postmortem identification of *A. marginale* can be established by staining blood smears with Giemsa or direct fluorescent stains. Peripheral blood is superior to organ smears. Brain smears are unsatisfactory. The technique is applicable to fetuses suspected of being aborted as a result of infection with *Anaplasma* sp. Nucleic acid-based tests may be used but are rarely needed for routine diagnosis at necropsy.

**Samples for confirmation of diagnosis**

- **Clinical pathology** – blood smears from cut surface of an ear (CYTO, FAT)
- **Histology** – fixed spleen, liver, bone marrow.

**DIFFERENTIAL DIAGNOSIS**

Other causes of hemolytic anemia.
TREATMENT

Treatment is with tetracyclines. Treatment of clinical disease can be with oxytetracycline, 6–10 mg/kg BW daily for three days, or a single injection of long-acting oxytetracycline at a dose of 20 mg/kg intramuscularly. The convalescent period is long. Concurrent administration of estradiol cypionate (14.3 mg/kg BW intramuscularly) appears to improve the rate of recovery by promoting parasitemia during treatment. Tetracycline treatment will not eliminate infection and immunity will persist.

Blood transfusions are indicated in animals with a PCV less than 15%. Rough handling must be avoided.

Imidocarb (3 mg/kg BW) is also an effective treatment for clinical cases and does not interfere with the development of acquired immunity to A. marginale.

The risk for infection in the rest of the herd should be assessed and, if necessary, temporary or prolonged protection should be provided. Protection can be provided by tetracyclines, or by vaccination.

Temporary protection in the face of an exposure risk can be achieved with a single intramuscular injection at 20 mg/kg BW of long-acting tetracycline. The results generally are good except when the cattle are exposed to infection during the 14 days prior to the treatment. Prolonged protection can be achieved by the intramuscular injection at 20 mg/kg BW of long-acting tetracycline every 28 days or by chlortetracycline in the feed at 1.1 mg/kg BW daily.

Elimination of infection cannot be achieved with tetracycline therapy. A trial testing the ability of oxytetracycline therapy to eliminate the carrier state examined therapy with 300 mg/mL oxytetracycline solution of administered at 30 mg/kg, by intramuscular (IM) injection for one day; the same preparation administered at 30 mg/kg, IM on day 0 and again on day 5; and a treatment with a 200 mg/mL solution of oxytetracycline administered at 22 mg/kg, intravenously (IV), q 24 h for 5 days (a treatment dose that corresponds with current Office International des Epizooties (OIE) recommendations for treatment prior to export). All treated cattle were still, PCR and cELISA positive 60 days after therapy and their carrier status was confirmed by inoculation of blood in splenectomized calves.

CONTROL

Methods for the control of anaplasmosis have not changed greatly over the past several decades and consist of arthropod control with acaricides, chemotherapy for prevention and vaccination. The eradication of anaplasmosis is not a practicable procedure in most countries at the present time because of the wide range of insects which are capable of carrying the disease, the long period of infectivity of carrier animals, and, in some areas, the presence of carriers in the wild animal population. In enzootic areas some benefit is derived from the control of ticks and other vectors and weekly dipping in an acaricide is used in tropical areas to control this and other tick-borne diseases.

General measures

The introduction of the disease into herds by carrier animals should be prevented by prior serological testing. Attention should also be given to preventing iatrogenic transmission with instruments used for injections or surgical operations by disinfection after use on each animal. This is particularly important in feedlots where introduced groups are often subjected to multiple vaccinations and implantation at a time when their resistance is lowered by transport and change of feed.

Movement of animals

Exposure-naive animals that are to be introduced into an enzootic area should be vaccinated. Some advantage can be gained when introducing animals into an enzootic area by limiting the introductions to animals of less than 2 years of age and by bringing them in when the insect population is least numerous.

Elimination of carriers

This is feasible in regions that are subject to only periodic incursions of infection and that do not have endemic tick vectors. It can be achieved by serologic testing and culling of reactors or treating them as outlined above to eliminate the carrier state.

Outbreaks

If an outbreak does occur, affected animals should be treated vigorously as described above and in-contact animals vaccinated and/or placed on a regimen of prolonged tetracycline protection. Subsequently all exposed animals should be tested serologically and the reactors treated or preferably salvaged. Prolonged treatment regimens can be used to provide protection to cattle in seasonal risk periods of transmission.

Chemotherapy

Chemotherapy for control is more commonly used in the United States than in other areas of the world. It can be of value in feedlot cattle but is not applicable to range cattle. It is expensive and carries the risk of causing selection of resistant strains.

Vaccination

Vaccines for the control of anaplasmosis are either live or killed vaccines. Both types use A. marginale from infected bovine erythrocytes and while both types induce protective immunity that reduces or prevents clinical disease neither type prevents cattle from becoming persistently infected with A. marginale. Cattle that have recovered from acute infection or immunized with killed vaccines are solidly protected against challenge with the homologous strain but are only partially protected against challenge with heterologous strains.

Most control programs in enzootic areas are based on increasing the resistance of the population by immunization. In any vaccination program particular attention should be paid to the animals at high risk, particularly animals brought in from non-enzootic areas, those in surrounding similar areas to which infection may be spread by expansion of the vector population under the influence of suitable climatic conditions, and animals within the area which are likely to be exposed to climatic or nutritional stress.

Killed vaccines

Killed A. marginale are usually in an adjuvant vehicle. The vaccine requires two doses, four weeks apart, the last dose given at least two weeks before the vector season. Subsequently booster doses should be given two weeks before the next vector season. The vaccine does not prevent infection but does significantly reduce the severity of the disease. It does have the advantage over the other vaccines of having a relatively short post-vaccination period when animals remain positive to serological tests. The duration of the immunity is at least 5 months.

There is a risk for neonatal isoerythrolysis. This can be reduced by vaccinating only empty cows and avoiding unnecessary booster injections. When this vaccine is used in the face of an outbreak, tetracyclines can also be given to provide temporary protection during the period of development of immunity; tetracyclines do not interfere with the development of this immunity.

Preliminary reports of the efficacy of DNA vaccines are not encouraging.

Live vaccines

A living A. centrale vaccine is used extensively in Australia, Africa, Israel, and Latin America, but not in the United States and there is some reluctance to introduce it into areas where A. centrale does not already occur.

Living A. centrale vaccine is prepared from the blood of infected splenectomized donor calves and is stored chilled or frozen. The vaccine causes a mild, inapparent disease, but does cause severe reactions in occasional animals. It is generally safe in young cattle. A single vaccination is used in endemic areas and the immunity is reinforced by continuous challenge and considered to persist for life in tick areas. A. centrale and A. marginale share immunodominant epitopes and have similar antigenic variation in major surface proteins which may play a role in the cross-immunity
that occurs. It is unclear whether A. centrale infection and immunity induced by the live vaccine in cattle prevents subsequent infection with A. marginale by the infection exclusion phenomenon.

The efficacy of this vaccine varies geographically. Vaccination with A. centrale reduces the severity of the reaction when infection with A. marginale occurs but does not give absolute protection. Protection against challenge in Australia is adequate in most cases, and certainly sufficiently virulent strains is often inadequate and highly virulent strains is often inadequate and better vaccines are required.

Tetracyclines will prevent establishment of infection and immunity by the vaccine and should not be administered for 3 weeks before vaccination.

**Living A. marginale** has been used as a vaccine but its administration is limited to the relatively resistant age group below 1 year of age, to the winter months when vectors are sufficiently rare to avoid the chance of spread to other age groups, and to circumstances where animals which react severely can be restrained and treated adequately. The method has the serious disadvantage of creating a large population of carrier animals which may subsequently spread the disease.

**Attenuated vaccines** have been attempted by irradiation of strains and passage of infection with a vaccine but its administration is limited for 3 weeks before vaccination.

Problems with live vaccines

All vaccines currently must be produced in live animals, which is expensive. With non-inactivated vaccines there is a risk of transmitting blood-borne viruses. In Australia, a single calf infected with bovine leukemia virus was unsuspectingly used in the production of A. centrale vaccine. The contaminated vaccine was given to 22 627 cattle in 111 herds and resulted in a high rate of infection with bovine leukemia virus in the vaccinated cattle. It is highly probable that a safe subunit vaccine, containing epitopes critical to effective immunity, will be developed in the near future.

**TICK-BORNE FEVER**

**Etiology** *Anaplasma phagocytophila*

**Epidemiology** *Anaplasma phagocytophila* occurs in the northern latitudes and is transmitted by *Ixodes ricinus* in UK and Europe and *Ixodes scapularis* and *I. pacificus* in the USA. Disease in cattle and sheep primarily reported from the UK and Europe. Seasonal occurrence associated with the feeding activity of the vector. More severe disease in naïve introduced animals. Increases susceptibility to other infections.

**Clinical Findings** Fever, depression, lethargy, polyneuropathy and fall in milk production in cattle.

**Pathology** Thrombocytopenia followed by more prolonged neutropenia and lymphocytopenia. The organism is demonstrable in the neutrophils and monocytes during each febrile period.

**Diagnostic confirmation** Demonstration of the *E. phagocytophila* in leucocytes at acute stage of the disease or serology retrospectively.

**Treatment** Oxytetracycline

**Control** Oxytetracycline during risk period.

**ETIOLOGY**

Tick-borne fever (also called pasture fever in cattle) is associated with infection with *Anaplasma phagocytophila*. *Ehrlichia phagocytophila*, *Cytocetes phagocytophila* which is an obligate intracellular parasite in the family *Anaplasmataceae*. *Anaplasma phagocytophila* and the human granulocytic ehrlichial agent (HGE) and *Ehrlichia equi* are morphologically identical, they have only minor variations in their 16S RNA genes and 100% identity in their GroE3L amino acid sequences, and so are now all classified as *Anaplasma phagocytophila*.

There are strains (variants) of *A. phagocytophila* that have biological and ecological differences, including variations in host pathogenicity, vectors, and geographical distribution. In sheep, different variants of *A. phagocytophila* may exist simultaneously in the same sheep flock.

Tick-borne fever is also used as a name for similar, but less well defined, diseases of ruminants that are associated with infection with related organisms such as *Anaplasma* (*Ehrlichia*). The following paragraphs are from other areas of the world such as India and Africa, and are transmitted by the ticks *Rhipicephalus appendiculatus*, *Amblyomma variegatum* and *Hyalomma truncatum*.
This description is of tick-borne fever associated with \textit{A. phagocytophilum}.

**EPIDEMIOLOGY**

**Occurrence**
Infection with \textit{A. phagocytophilum} occurs in a wide range of mammalian hosts including humans, dogs, sheep, cows, horses, wild deer and rodents. The association of \textit{A. phagocytophilum} with human granulocytic ehrlichiosis in the mid-1990s has led to much activity defining its geographical occurrence by serological surveys or detection in ticks by molecular methods. These studies have determined that the organism is present where the host ticks are present in Europe, Iran, North America and probably Asia.

However, the disease tick-borne fever, as opposed to infection, occurs primarily in certain areas of the United Kingdom, Ireland, Norway, Finland, France, Germany, Spain, and Switzerland. Because ticks favor particular optimal environmental conditions, the geographic distribution of the ticks is usually restricted to a specific area (small or large) and tick-borne fever only occurs in these areas. Within these areas infection can be intense and in the endemic coastal area of Norway close to 100\% of sheep grazing \textit{Ixodes} infested pastures are infected. Tick-borne fever has a seasonal occurrence in association with the feeding activity of the vector tick. Infection can be endemic in affected areas.

Sheep, cattle, goats, deer and reindeer may be infected. The disease has long been known as a disease of sheep but in recent years is being recognized as a common infection in cattle in at-risk areas. The incidence rate of infection is high but clinical disease may be mild and not easily observed in many areas where this disease occurs, as these area are commonly wild with little human habitation and little frequent observation of at-risk livestock. Infection, as determined by seropositivity, can occur in sheep that have had no clinical evidence of disease because of the existence of variants with low pathogenicity.

**Source of infection and transmission**

In Europe, \textit{E. phagocytophila} is transmitted by the three host tick \textit{Ixodes ricinus} which requires a single blood meal at each stage of development. The tick feeds for approximately 3 weeks every year and completes its life cycle in 3 years. The larval and nymphal stages will feed on any vertebrate but the adult female will engorge and mate only on larger mammals.

A. phagocytophilum infect and multiply in the organs of ticks, in particular the salivary glands which enables the transmission to vertebrate hosts during feeding. The tick becomes infected by feeding on an infected host and there is trans-stadial but not transovarial passage of the organism. It is estimated that the majority of ticks are infected with the organism in enzootic areas and one study of ticks from a field site found 44\% of nymphs and 32\% of adults infected but no infected larval stages. There is a close relation tick density and the proportion of sheep and ticks infected with \textit{A. phagocytophilum} but it is non-linear and complex.

In the USA, \textit{Ixodes scapularis} has been implicated in transmission of the organism in eastern USA and \textit{Ixodes pacificus} on the west coast, as have \textit{Ixodes persulcatus} and \textit{Haemaphysalis longicornis} in Asia but clinical disease in ruminants is not a feature in these locations.

**Congenital infection**
of a calf has occurred following experimental infection of the dam in late pregnancy and the organism is also present in leukocytes in milk during the acute phase of the disease, but the significance of this in the epidemiology of the disease is not known. A few as one \textit{A. phagocytophila}-infected cell may be enough to transmit infection and use of a single needle between sheep in a group could possibly transmit infection.

It has been suggested that the presence of ticks in migratory birds could spread infection of this agent to other geographic regions.

**Experimental reproduction**
The disease can be readily reproduced experimentally. The severity of the clinical response of sheep following experimental infection is not dose dependant and there is no dose effect on the degree of parasitemia or neutropenia.

**Host risk factors**
Calves and lambs are much more susceptible than adults although clinical disease may be less severe in very young lambs possibly due to mitigating effects of premunition. Hyperimmunization of the pregnant ewe will produce high levels of colostral antibody that will protect the lamb against experimental challenge. However, in the field colostral immunity does not protect against infection and lambs born of ewes raised in endemic areas become infected. Natural infection is followed by a state of low-grade premunition due to the presence of the organism in the blood which provides partial resistance to subsequent infections, the disease manifesting itself in a less severe form. Once infected, animals probably remain carriers for life and act as reservoirs of infection for new generations of ticks.

The case fatality is very low and most reported mortality is in association with intercurrent disease. A significant indirect effect of tick-borne fever is that it increases the susceptibility of lambs to \textit{Staphylococcus pyemia}, \textit{Staphylococcal pneumonia}, septicemic and pneumatic \textit{pateurlosis}, louping-ill and possibly other diseases. The mortality rate is negligible in cattle but may be higher in sheep.

**Pathogen risk factors**
The activity of the tick is seasonal and consequently tick-borne fever has a seasonal occurrence. The tick is active at temperatures between 7-18\degree C and most ticks feed in the spring, with peak activity dependent upon the latitude and elevation of the pasture but generally occurring in April and May. In some areas there is a second period of activity of a separate population of \textit{I. ricinus} in the autumn during August and September. Clinical signs in cattle occur predominantly in spring, one to two weeks after they start to graze.

**Zoonotic implications**

Human granulocytic ehrlichiosis is associated with \textit{A. phagocytophilum} and was first described in the USA in 1994 and in Europe in Slovenia in 1997. It presents most commonly as an undifferentiated, febrile, potentially severe illness occurring in summer or spring associated occupational or recreational activities that allow exposure to infected ticks. There is no recognized direct zoonotic risk from exposure to infected animals but there is evidence that sheep may be one of the maintenance hosts for the organism.

**PATHOGENESIS**

A phagocytophilum infect and replicate within neutrophils where they live in cytoplasmic vacuoles to form clusters called morulæ. They are able to evade activation of the cytotoxic arsenal of the neutrophil but they do perturb neutrophil function.

Tissue pathology is not associated with direct \textit{A. phagocytophilum}-mediated injury but results from immunopathologic mechanisms associated with cytokine and chemokine production.

Fever develops in association with parasitemia and is the prominent clinical abnormality in the experimental disease. It persists for approximately 8 days, may exceed 41\degree C, and is accompanied by depression. While this syndrome is of limited importance in the experimental setting, the occurrence of fever, dullness, and depression of the sucking drive can be a significant influence on the viability of lambs in the cold, wet, rough-grazing areas where this disease commonly occurs and may contribute to lamb mortality.

Tick-borne fever produces profound effects on immunological defense systems. There is a significant lymphocyte development that develops 6 days after infection and which affects all T- and B-lymphocyte
subsets. There is also a prolonged neutropenia lasting for 2–3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are parasitized from the onset of the parasitemia and have impaired function. The antibody response of infected sheep to immunogens such as tetanus toxoid is also impaired.

Field observations and experimental challenge has shown that infected lambs are more susceptible to disease and mortality from intercurrent infections. The ability of an infection with A. phagocytophila to predispose to secondary disease varies with the strain of the organism which may explain why secondary complications are not observed in all flock infections with tick-borne fever. There is a clear relationship between infection with E. phagocytophila and susceptibility to infection with Staphylococcus aureus and the resultant disease, tick pyemia. This is established both by epidemiological and experimental studies.

Concurrent infection of sheep with the agent of tick-borne fever potentiates the pathogenicity of louping-ill virus, in experimental infections, to result in more severe disease and a higher mortality. Both diseases are transmitted by I. ricinus. However, in areas where both diseases are endemic, colostral immunity will delay infection of lambs with the louping-ill virus until the second year of exposure to the vector tick while allowing infection with tick-borne fever. Simultaneous primary infection with both agents may be uncommon in nature.

Infection also facilitates invasion and systemic mycotic infection with Rhizomucor pusillus resulting in diarrhea and dysentery and a high mortality rate. Concurrent experimental infection of sheep with E. phagocytophila and Chlamydia psittaci results in chlamydial pneumonia and simultaneous infection with parainfluenza-3 (PI-3) virus potentiates the pathogenic effect of PI-3 virus. The immunosuppressive effect of tick-borne fever is believed to have resulted in the exacerbation of latent Brucella abortus in a naturally occurring abortion outbreak in cattle. Concurrent infection of tick-borne fever and Listeria monocytogenes or Pasteurella haemolytica promotes the respective septicemic disease in lambs.

CLINICAL FINDINGS

Disease is generally benign but infection can produce abortion and can cause significant loss of weight in lambs and calves.

Cattle

In cattle there is an incubation period of 5–9 days followed by a rise in temperature to about 40.5°C (105°F) which persists for 2–12 days and for a longer period in late pregnant cows than in lactating cows.

The temperature falls gradually and is followed by a secondary febrile period and, in some cases, yet further episodes of pyrexia. During each febrile period there is a marked fall in milk yield, lethargy and polyptemia and in experimentally produced cases, a mild cough although feed intake is not reduced. The fall in milk production can be severe and may be the first indication of infection. Pregnant cattle, in the last two months of pregnancy, and placed on tick-infected pastures for the first time, commonly abort and occasionally animals die suddenly. The abortions occur shortly after the systemic disease. Some calves are born alive but they are weak and die.

Sheep

In sheep the syndrome is similar to that observed in cattle except that respiratory distress is not observed. However, there can be marked differences in clinical manifestation, neutropenia, antibody response, with different variants of A. phagocytophilum. The reaction in young lambs is quite mild and manifested only by a fever which fluctuates between 40–42°C for up to 10 days. Ewes exposed to the disease for the first time commonly experience outbreaks of abortion and affected rams are temporarily infertile. Abortion is a major manifestation in northern Spain whereas in the Scandinavian countries the main consequence of infection is immunosuppression leading to secondary infections with Staph. aureus (tick pyemia) and Pasteurella hemolytica.

Goats

Tick-borne fever in goats is characterized by high fever, dullness and tachycardia. See page 1464 for a description of the disease in horses.

CLINICAL PATHOLOGY

At the commencement of the fever there is a severe but transient thrombocytopenia and this is followed by more prolonged neutropenia and lymphocytopenia. The anaplasmae are demonstrable in the neutrophils and monocytes during each febrile period and for a few days afterwards in cattle and for several weeks in sheep; they can be detected as intracytoplasmic inclusion bodies in Giemsa stained blood smears, or by PCR.

Serological diagnosis is possible using counter-immunoelectrophoresis which detects IgM antibody or indirect immunofluorescence using cytoplasmic preparations of blood granulocytes, which detects IgG. Antibody is at a high level at the second week after experimental infection with both tests and is detectable for 6–8 weeks with counter-immunoelectrophoresis and for at least 18 weeks with the indirect fluorescent antibody test. ELISA is also available for serological diagnosis.

Transmission of the disease for diagnosis may be effected by the intravenous injection of blood taken at the height of the fever.

NECROPSY FINDINGS

There are no gross changes other than splenomegaly in sheep, and histologically the only characteristic lesion is a depletion of lymphocytes from lymphoid tissue.

Multifocal leucomacular spongy change of white matter and swelling of oligodendrocytes is found in the brain of aborted lambs probably the result of fetal anoxia.

DIFFERENTIAL DIAGNOSIS

- The geographical restriction of the disease and its relation to tick infestation are diagnostic features but the clinical signs are quite non-specific.
- The disease in cattle has some similarity to bovine pestelet fever (Ondiri disease), associated with E. ondri, which occurs only in Kenya.

TREATMENT

The best results are with tetracyclines or sulfadimidine although cattle may recover without therapy. In sheep, a single dose of long acting tetracyclines (20 mg/kg IM) or a 5-day course with oxytetracycline (10 mg/kg IV daily) given during the acute phase of the disease is effective in treatment but infection is not eliminated in a significant proportion of sheep. In goats good results are provided by single doses of oxytetracycline (10 mg/kg BW intravenously) or a potentiated sulfadimidine containing trimethoprim and sulfadimidine, and sulfamethylphenazole (20, 50, and 50 mg/kg BW respectively); ampicillin is ineffective. The anaplasmae persist in treated animals which may subsequently suffer a relapse.

CONTROL

Control of tick-borne fever depends upon control of the tick population. The annual dipping of ewes with organophosphates or synthetic pyrethroid acaricides will help reduce tick numbers and the double dipping of lambs during the tick season will help reduce disease in the lambs but can be difficult to achieve in the terrain and with the management practices of affected areas. Disease is reduced if the flock can be kept off the tick-infested pastures until the lambs are 6 weeks old and if the flock is dipped prior to introduction to the pasture. In some areas it may be possible to reduce tick numbers by pasture management systems that disturb the pasture microclimate required by the tick.

The disease can be more severe when adult animals are exposed to infection for...
the first time and naïve late pregnant cattle should not be introduced to tick-infested pastures during the tick rise periods. A single administration of 20 mg/kg of long-acting tetracycline is reported to provide protection against experimental challenge for periods up to 3 weeks. The prophylactic administration of long-acting tetracycline to lambs and to calves during the season of tick activity is reported to reduce mortality and improve growth rates over untreated controls.

**HEARTWATER OR COWDRIOSIS**

**ETIOLOGY**

*Ehrlichia (Cowdria) ruminantium*, a rickettsial organism

**Vectors** *Amblyomma variegatum* and *A. haemaphysana*

**Epidemiology**

Endemic disease of cattle, sheep, goats, and wild ruminants in Africa and the Caribbean; high mortality in exotic animals

**Pathogenesis**

Tick inoculation → local lymph node → blood → endothelial cells → vascular permeability → clinical signs and lesions.

**Clinical signs**

High fever, nervous signs, diarrhea and death if acute; may be mild and inapparent

**Clinical pathology**

Non-specific

**Diagnosis**

Rickettsial colonies in capillary endothelium (brain preparations)

**Lesions**

Ascts, hydrothorax, hydropericardium and severe pulmonary edema

**Differential diagnosis list**

Anthrax, rabies, cerebral babesiosis, cerebral thileriosis, meningitis or encephalitis

**Treatment**

Short- and long-acting tetracyclines

**Control**

Vaccination based on infection and treatment methods, tick control and chemoprophylaxis

**ETIOLOGY**

*Ehrlichia (Cowdria) ruminantium* is a Gram-negative, intracellular rickettsial organism in the tribe *Ehrlichiae*. It occurs in colonies or morulae with a predilection for the vascular endothelium and stains blue with erythrosin. The organism is coccoid, 0.2-0.5 microns in diameter. It can now be cultivated in vitro and it can also grow in the tribe *Ehrlichiae*. It occurs in colonies in capillary endothelium (brain preparations) or morulae with a predilection for the vascular endothelium and stains blue with erythrosin. It is one of the main causes of death in imported breeds of cattle, sheep and goats in endemic areas. Heartwater has been diagnosed recently in the island of Mayotte in the Indian Ocean.

**MEASURES OF OCCURRENCE**

In endemic areas, morbidity and mortality rates are low, but the percentage of sera positive titers for heartwater could be as high as 100% in adults, depending on the abundance of tick vectors. Case mortality can be as high as 100% in peracute cases in sheep and goats and as low as 0-10% in cattle. The disease is less severe in indigenous breeds and related game animals reared in enzootic areas, some of which may become symptomless carriers. The N'Dama breed in West Africa is said to be well adapted to heartwater, partly because it can resist tick burdens under traditional farming system.

**METHOD OF TRANSMISSION**

Heartwater is transmitted by many ticks of the *Amblyomma* genus, especially *A. variegatum* (the tropical bont tick) and *A. haemaphysana*, and their geographic distribution is spreading. A single infected tick can transmit the disease to cattle. In the Caribbean, cattle egrets are suspected to spread *A. variegatum* between islands. Consequently, heartwater is considered a threat to the American mainland where potential vectors are present but do not harbor the disease or where the vector may be introduced and become established. Infection in ticks is transmitted trans-stadially and possibly transovarily. Vertical transmission to calves in colostral milk has also been reported. Several wild ruminants can be infected and become subclinical carriers and reservoirs. Ticks feeding on them can transmit the disease to domestic ruminants. The organism does not infect humans.

**RISK FACTORS AND IMMUNE MECHANISMS**

Animals at greatest risk are exotics imported into endemic areas and at times when the vector population is high, usually during the rains. Angora goats are also highly susceptible and therefore difficult to immunize by the current method of infection and treatment. Cattle and sheep recovering from the disease are immune for 6 months to 4 years but may be carriers for 8 months or longer. An age-dependent resistance has long been recognized and young animals were believed to have innate resistance. This was later shown to be due to low-grade infection of the young in colostral cells.

**ECONOMIC IMPORTANCE**

Heartwater is the most important rickettsial infection of ruminants in Africa and the second most important tick-borne disease after East Coast fever. In southern Africa, it is regarded as the most important disease of ruminants. In general, heart-
Heartwater or cowdriosis

tetanus, cerebral forms of theileriosis, babesiosis, trypanosomosis, meningitis, listeric or other encephalitis, hypomagnesemia and poisoning with strychnine, lead and organophosphates. Appropriate laboratory tests are utilized to eliminate these differentials.

TREATMENT
Field cases of heartwater are difficult to treat successfully because available drugs are effective only in early febrile stages before neurological signs develop. In the early stages, short-acting tetracyclines at 10–20 mg/kg BW and long-acting forms at reduced doses are effective. Sulphonamides can also be used in the early stages but are less effective. Hyperimmune serum is said to be of no curative value. Supportive therapy to reduce either the pulmonary edema or the neurologic signs or to stabilize membranes in general are being investigated but with little success.

Chemoprophylaxis involves administration of tetracyclines or subcutaneous implantation of oxytetracycline in susceptible animals when they are introduced into an endemic area. Results are not always predictable.

CONTROL
Past efforts to control heartwater were based on intensive acaricide treatment in endemic areas. It involved frequent use of acaricides (plunge dipping) up to 52 times a year. This has now been shown to be environmentally unfriendly, economically unsustainable, and would invariably lead to animals that remained always susceptible. For example, it was observed in Zimbabwe that large farms applying acaricides very frequently (more than 30 times per annum) had higher morbidity and mortality than farms applying acaricides less frequently. What is advocated today is integrated control based on the establishment of endemic stability by vaccination or natural challenge. Vaccination is based on infection and treatment regimen that was first developed more than 50 years ago. It involves an intravenous injection of virulent organisms in cryopreserved sheep blood, followed by treatment with tetracyclines at the first indication of fever. The exposure of calves and lambs up to 3 weeks of age, without treatment, is considered optimal for the development of resistance but kids may still be susceptible. Vaccination may lead to some deaths, the immunity may wane in absence of reinfec tion, and animals may become carriers. More recently, cattle were successfully immunized for up to 10 months with a killed vaccine from a lysate of E. ruminantium.
nantium formulated in Freund's adjuvant. In another study, the use of inactivated vaccines from cell-cultured E. ruminantium combined with an adjuvant led to a reduction in mortality from heartwater in cattle, sheep, and goats exposed to field challenges in Botswana, Zambia, Zimbabwe, and South Africa. Experimental studies using DNA recombinant vaccines so far have met with only limited success.

For tick control, flumethrin 1% pour-on at 45 days interval was found to provide effective protection of Friesian/Zebu cattle from tick infections, but it must be applied correctly at the recommended dose. Pure Zebu and N'Dama cattle would probably require less frequent applications. Flumethrin pour-on is gradually replacing plunge dipping for the control of ticks and tickborne diseases in general. Other than routine surveillance, there are no special biosecurity concerns with heartwater, since transmission requires interaction of hosts, vectors, and the agent.

EQUINE GRANULOCYTIC APAKLASMOSIS (EQUINE GRANULOCYTIC EHRLICHIOSIS, ANAPLASMA PHAGOCYTOPHILA)

Anaplasma phagocytophila causes disease of horses, humans, dogs, cattle, cats, and other mammalian species, that is characterized by fever, depression, limb edema, icterus and ataxia. The disease is described in horses with emphasis on that occurring in horses. The Tick-bone fever description of the disease in other species.

ETIOLOGY
The disease in horses is associated with the same agent that causes human granulocytic ehrlichiosis (HGE). The organisms 

REFERENCES
Anaplasma phagocytophila infects domestic ruminants in Europe where it causes tick-borne fever. However, cattle infected with HGE agent or *A. phagocytophila* isolated from horses with the disease in the United States do not develop clinical signs of disease nor do they have detectable *A. phagocytophila* morulae in blood, although they do seroconvert. This study, and the low seroprevalence of antibodies to *A. phagocytophila* in cattle in California indicate the organism rarely, if ever, causes disease in cattle in these geographic regions.

Infection in horses is followed by a solid immunity and recovered animals are resistant to the disease for at least 20 months although it is suggested that reinfection and disease can occur. Serum antibodies persist for at least 300 days after infection in some horses but decrease to low levels in most horses by 200 days after infection.

**Transmission**

As discussed above, transmission is through the bite of an infected tick. Transmission through use of blood contaminated veterinary equipment or by blood transfusion is possible, the later being used to induced disease in experimental challenges. Perinatal transmission of *A. phagocytophila* is reported in humans.

**Morbidity and mortality**

The case fatality rate is low, approximately 4%, and deaths of horses with uncomplicated disease are rare.

**Zoonotic potential**

There is no evidence that infection spreads directly from infected horses or dogs to humans. However, dogs have been suggested to be sentinel animals in that humans in areas in which dogs have a high prevalence of antibodies in serum to *A. phagocytophila* might be at increased risk of infection from bites of infected ticks.

**PATHOGENESIS**

The pathogenesis of the disease is poorly understood. Following experimental infection, horses have organism detectable by PCR beginning 5 days after infection, with development of fever and depression 7–8 days after infection. Inclusions in granulocytes are detectable beginning 9 days after infection, at which time there is edema of the limbs. The disease in horses is associated with rapid changeover of expressed p44 genes such that there is a marked antigenic variation in the major surface protein, p44, during infection in an animal. The rapid changeover of expression of p44 is attributed to development of specific antibody to the hypervariable region of p44. Infection in sheep results in immune suppression secondary to granulocytic and lymphocytic leukopenia, impaired antibody production, reduced lymphocyte response to mitogens, and a decreased oxidative burst activity of neutrophils. The prominent clinical sign of edema is likely related to the vasculitis that is characteristic of the disease.

**CLINICAL SIGNS**

The incubation period for the spontaneous disease is less than 2 weeks. Subclinical infections are believed to be common, based on the number of horses with serologic evidence of infection but no history of disease. Clinically there is high fever of 40–42°C (104–107°F) followed by mucosal pallor, jaundice, anorexia, depression, increased respiratory movement, incoordination and reluctance to move and, after 3–4 days, edema and heat of the extremities. There may be petechial hemorrhages on mucosal membranes. The edema persists for 7–10 days and clinical signs resolve in 14 days. Clinical disease is more severe in horses over 3 years of age and is minor in young horses. Severely affected horses can have signs consistent with neurologic disease, including ataxia, defects in conscious proprioception, and recumbency.

**Arrhythmias** may occur during the acute phase of the disease. Chronic infection and disease is not recognized.

**CLINICAL PATHOLOGY**

Hematologic examination may reveal a mild anemia and leukopenia. Thrombocytopenia is common in the acute stage of the disease. There are no consistent serum biochemical abnormalities.

**Positive identification** of the disease is made on the presence of inclusion bodies (morulae) in the cytoplasm of neutrophils and eosinophils. Careful and protracted microscopic examination of a blood smear, stained with Giemsa, may be necessary to identify the inclusions (morulae). The inclusions are apparent as pleomorphic, blue-gray color bodies, often in a spoke wheel formation, in the cytoplasm of granulocytes. The number of infected cells may be quite small and examination of a buffy coat preparation may increase the sensitivity of the test.

**Diagnosis** is achieved through use of a polymerase chain reaction test to identify *Anaplasma phagocytophila* DNA in blood samples of infected horses and by demonstration of an increase in antibody titer detected by indirect fluorescent antibody staining. However, antibody titers are low to undetectable in approximately 44% of horses with the onset of clinical signs, and reach a maximum within one month of infection. An ELISA that detects antibodies against the p44 surface antigen of *A. phagocytophila* is suitable for use in dogs and horses.

**NECROPSY EXAMINATION**

At necropsy there are petechiae and edema of the legs and at histological examination there is a vasculitis. There are often inflammatory lesions in the brain, heart and kidneys.

**DIFFERENTIAL DIAGNOSIS**

Differential diagnoses include: equine infectious anemia, which has a much more protracted course and does not respond to treatment; purpura hemorrhagica, which is often associated with infectious upper respiratory tract disease; liver disease, viral encephalitis; equine herpesvirus 1 myeloencephalopathy, *rabies*, botulism, and equine viral arteritis.

**TREATMENT**

The specific treatment is oxytetracycline (7 mg/kg BW IV, every 24 hours) for approximately 5–7 days. Penicillin, streptomycin and chloromycetin are not effective. The response to treatment with oxytetracycline is rapid and the fever is reduced or eliminated in 12–24 hours, and signs of the disease resolve within 5–7 days in most horses. Inclusion bodies are difficult to find 24 hours after beginning treatment. Without treatment the disease is usually self-limiting to 2–3 weeks.

**CONTROL**

There is no vaccine, and specific control measures cannot be recommended at this time, although minimizing access of ticks to horses would appear prudent. There is no need to isolate infected horses.

**REFERENCES**

Occurrence
Equine neorickettsiosis is recorded in the United States, Canada, Europe, Uruguay and southern Brazil. While it might have wider occurrence, evidence of infection based on the commonly used indirect fluorescent antibody test should be interpreted with caution because of the high rate of false positive results. The highest prevalence of disease is near large rivers, apparently related to the infection of horses by ingestion of infected aquatic insects, although the disease can occur elsewhere. Clinical disease is sporadic and seasonal with the predominance of cases occurring during the summer and the autumn in areas with cool to cold winters. In warmer areas, such as Florida and Texas, cases occur year round. The prevalence of horses in the mid-west and east coast of the United States with antibodies to *N. risticii* varies with geographical region, but can be as high as 86% of horses tested, although the overall rate appears to be closer to 25%. The prevalence of horses with serological evidence of exposure is much less in California. There is a marked seasonal variation in the prevalence of seropositive horses, with the highest prevalence being in the summer months (July and August) and the lowest prevalence being in the winter.

Animal risk factors
Clinical disease is believed to be uncommon in horses under 1 year of age, although peracute disease can occur in foals, and there is no age difference in prevalence of disease in adult horses. Similarly, there is no evidence that breed and sex influence susceptibility to disease. The risk for disease is greatest in horses housed on premises with a history of previous infection or those that have other livestock. The clinical attack rate varies considerably, but estimates range between 0.44 and 19 cases per year per 1000 horses at risk. During epidemics, the clinical attack rate may be as high as 20–50% of horses on affected farms. Case fatality rates as high as 30% were initially reported for horses with clinical disease but with the subsequent improvement in diagnosis and early treatment the case fatality rate is currently closer to 7%.

The risk of horses being seropositive in some areas is related to breed (Thoroughbreds are three times more likely to be seropositive than are non-Thoroughbreds and non-Standardbreds), sex (females are 2.7 times more likely to be exposed than are stallions and geldings), and age (increasing risk up to 12 years of age). Horses that have had clinical signs compatible with neorickettsiosis are more likely to be seropositive than are horses with no such history.

Transmission
The disease is infectious but not contagious. Horses develop infection and disease after ingestion of aquatic insects including caddis flies (*Dicosmoecus gibripes*). The disease can be transmitted experimentally to horses by parenteral administration of *N. risticii* or blood from infected horses. Studies of a tick (*Dermacentor variabilis*), black flies (*Simulium* spp.), fleas, flies (*Tabanus* spp., *Hybomitra* spp., *Stomoxys* spp., *Haematobia* spp.), and mosquitoes, have failed to demonstrate transmission of infection.

The complete life cycle of *Neorickettsia risticii* has not been elucidated, but it is known that the organism infects trematode stages ( cercariae and xiphidiocercariae) found in freshwater snails (*fugu* sp. in California and *Elima* sp. in Ohio). *Neorickettsia risticii* infects metacercariae found in adults and juveniles of aquatic insects including caddis flies (*Trichoptera*), mayflies (*Ephemeroptera*), damselflies (*Odonata, Zygoptera*), dragonflies (*Odonata, Anisoptera*), and stoneflies (*Plecoptera*). *N. risticii* DNA has been detected in trematodes (*Lechithodendriidae*) infecting bats and swallows. *N. risticii* DNA is present in eggs of the trematodes (*Acantharia* sp. *oregnense*) found in bats demonstrating vertical (adult to egg) transmission of infection in trematodes. Furthermore, *N. risticii* DNA was detected in the blood, liver or spleen of bats infected with the trematode, suggesting that *N. risticii* can also be transmitted horizontally from trematode to bat. These results indicate that the trematode *A. oregenense* is a natural reservoir and probably a vector of *N. risticii*. This information suggests that insectivorous bats and birds are the definitive hosts of trematodes that maintain the natural reservoir of *N. risticii*. Briefly, it appears that horses are accidentally infected by *N. risticii* that normally cycles between trematode life stages in bats, fresh water snails, and aquatic insects.

Infected horses develop sterile immunity and so are unlikely to be a source of subsequent infection.

PATHOGENESIS
Infection is followed by monocyte-associated bacteremia and the organism is present in monocytes, macrophages and the glandular epithelial cells of the intestinal tract. The number of *N. risticii* in blood is greatest before the development of clinical signs, which in experimentally infected horses and ponies occurs approximately 19 days after infection by ingestion of infected aquatic insects. The prominent clinical sign of diarrhea is due to colitis and typhlitis and is associated with an neorickettsi- induced disruption of sodium and chloride absorption by the large
Equine neorickettsiosis (equine monocytic ehrlichiosis, equine ehrlichial colitis, Potomac horse fever)

**Clinical Findings**

The classic manifestation of *N. risticii* infection is fever, depression, anorexia, diarrhea, colic, and laminitis. However, infection can result in a variety of clinical abnormalities ranging from inapparent infection, through transient fever and depression, to the severe signs described above. Equine neorickettsiosis should be considered in any horse living in an endemic area that demonstrates fever and depression.

In naturally occurring cases of severe clinical disease there is typically an acute onset with depression, anorexia, tachycardia, congested mucous membranes and fever up to 107°F. There are decreased intestinal sounds on abdominal auscultation in the early stages of the syndrome and subsequently tinking sounds prior to the onset of diarrhea which usually occurs 24-72 hours later. The severity of the diarrhea varies but it is usually profuse and projectile. It persists for up to 10 days and there may be sufficient fluid loss to result in severe and rapid dehydration and hypovolemic shock. Colic is a presenting sign in some horses and may be mild or present as an acute abdomen. Laminitis occurs in up to 40% of horses and is usually apparent within 3 days of initial signs of disease. There can also be subcutaneous edema in the ventral abdomen and limbs. Less severe clinical manifestations of infection include the occurrence of fever and anorexia without other signs, or the occurrence of mild colic or subcutaneous edema.

Abortion occurs as a result of *N. risticii* infection and, in experimental infections, occurs 65–111 days after infection of the dam. The dams that aborted all became clinically ill after infection, but clinical signs of disease had resolved at the time they aborted. Abortion was presaged by ventral edema and enlargement of the udder, and placenta was retained in some cases.

**Clinical Pathology**

**Hematological examination** usually reveals leukopenia (<5000 leukocytes per μl) with neutropenia and a marked left shift, mild thrombocytopenia, and hemococoncentration (hematocrit 50–60%, 0.5–0.6 L/L). **Serum biochemical analysis** often reveals hyponatremia, hyperkalemia, hypochloremia, metabolic acidosis and azotemia. **Peritoneal fluid** is usually normal.

**Diagnostic confirmation** is achieved by demonstration of *N. risticii* in blood or feces, or serological evidence of infection, in horses with clinical signs compatible with the disease. Routine diagnosis is based on demonstration of a high serum antibody titer on the indirect immunofluorescent antibody (IFA) test. Most horses with disease due to *N. risticii* have titers ≥1:80 at the onset of clinical signs while horses with titers ≤1:40 probably do not have the disease. The presence of a high titer at the time of onset of clinical signs is a result of the 8–12 day incubation period during which there is a high level neorickettsemia and the production of a strong IgM antibody response. The IgM antibody response wanes rapidly and may be undetectable by 60 days after infection, although a prominent IgG response occurs. Therefore, by the time clinical signs are apparent the horse has a high titer that might decline, making the use of acute and convalescent (2 weeks after clinical signs resolve) serum titers potentially misleading. A rising titer in samples collected several days apart soon after the onset of disease is indicative of the disease, but a declining titer does not rule it out. The IFA test performed in some laboratories has a high rate of false-positive reactions.

Detection of the organism in white blood cells by microscopic examination of stained blood smears is usually not possible because of the low level of infection of blood monocytes. The organism can be cultivated but this is time consuming and expensive. However, a test that detects the presence of *N. risticii* nucleic acid by the polymerase chain reaction has a sensitivity similar to that of blood culture in experimental infection. Similarly, *N. risticii* can be detected by a polymerase chain reaction test in feces of horses with disease.

** Necropsy Findings**

The gross changes in horses dying of EME usually include subcutaneous edema of the ventral body wall and a very fluid consistency to the contents of the large bowel. Congestion, hemorrhage and mucosal erosions can occur throughout the alimentary tract but are concentrated in the cecum and colon. The mesenteric lymph nodes are often swollen and edematous. There may be lesions of laminitis. Histologic examination confirms the alimentary mucosal erosion and ulceration, which is accompanied by an infiltrate of a mixed population of leukocytes within the lamina propria and submucosa. The causative organisms can be demonstrated in tissue sections using Steiner’s silver stain. Detection using electron microscopic or PCR techniques are other options.

Fetuses that are aborted as a result of *N. risticii* infection of the dam have histologic evidence of enterocolitis, perportal hepatitis and lymphoid hyperplasia with necrosis of mesenteric lymph nodes.

**Treatments**

The specific treatment of equine neorickettsiosis is oxytetracycline (6.6 mg/kg BW IV every 24 hours for 5 days) and horses treated early in the disease respond well. Given the effectiveness of oxytetracycline in the treatment of the disease and the lack of clear evidence that oxytetracycline at the recommended dose induces or exacerbates diarrhea, this drug should be administered to all horses that live in an endemic area and that develop signs consistent with equine neorickettsiosis. Treatment does not interfere with the development of immunity. Other antibiotics that have been used include combinations of a sulfonamide and trimethoprim or rifampin and erythromycin. Doxycycline has been used, but intravenous administration is associated with cardiovascular abnormalities and sudden death.

Treatment of horses with acute diarrhea is discussed under Acute diarrheas of horses. Prophylaxis for laminitis may be useful.

**Differential Diagnosis**

The main differentials are as follows (Table 5.14):

- Diarrhea due to: salmonellosis, *Clostridium difficile* colitis, massive emergence of hypobiotic cyathostomes, colitis X, and antibiotic-induced colitis
- Abortion due to: EHV-1, leptospirosis, congenital anomalies, and *Salmonella* abortus equi

**Samples for postmortem confirmation of diagnosis**

The parasite can be demonstrated in cecum, colon, and mesenteric lymph node by a polymerase reaction test or electron microscopy. Formalin-fixed tissue for light microscopy should include cecum, colon, liver and mesenteric lymph node.
not complete and wanes within 6 months. In an area with a low attack rate of the disease (0.44–1.7 horses/1000 per year) the risk of neocicketiosis in horses vaccinated once per year is almost identical (odds ratio = 0.93) to that of unvaccinated horses, and there is no difference in the severity of the disease in vaccinated and unvaccinated horses. Furthermore, it is more economical not to vaccinated horses in areas with a low attack rate. 

In an area with a low attack rate of the disease, vaccination of two doses once per year is almost identical (odds ratio = 0.93) to that of unvaccinated horses. 

REFERENCES

ETIOLOGY

Q fever is a zoonosis associated with Coxiella burnetii which is an obligate intracellular parasite classified within the family Rickettsiaceae and which can be divided into six genomic groups on the basis of restriction fragment length polymorphism. Unlike other Rickettsiaceae members C. burnetii it is quite resistant to environmental influences and is not dependant upon arthropod vectors for transmission. C. burnetii displays two antigenic phases, phase 1 and phase 11. Phase 1 organisms are more infectious.

EPIDEMIOLOGY

Occurrence

The organism has worldwide distribution although a large serological survey argues that it is not present in New Zealand. 

C. burnetii cycles in a wide variety of wildlife species and their ectoparasites. The infection also cycles in domestic animals; cattle, sheep and goats are the main livestock reservoirs of infection for humans. 

Rates of infection in farm animals vary considerably between locations, between countries and with time as there appears to be cycles of infection within regions. In cattle, prevalence figures range from 6–82% of cattle and 23–96% of herds seropositive depending upon location and country. Seropositivity rates in sheep and goats are similar but also vary according to year and region. There is little information on management or other factors that might influence this variation in prevalence but one study found a significantly higher prevalence in housed cattle compared to cattle at pasture kept at pasture.

Source of infection and transmission

Infection and transmission is by direct contact and by inhalation. Infection of non-pregnant animals is clinically silent and is followed by latent infection until pregnancy when there is recrudescence with infection in the intestine, uterus, placenta and udder and excretion from these sites at parturition. The organism is present in high concentration in the placenta and fetal fluids, and subsequent vaginal fluids, is also excreted in urine and is present in the feces of sheep from 11–18 days post partum. Infection can result in abortion, stillbirths or poorly viable lambs but commonly the neonates of infected, excreting, ewes are born clinically normal. Abortion usually does not occur at successive pregnancies but there can be recrudescence of infection and excretion at these pregnancies, especially the one immediately following. 

Goats also excrete the organism in vaginal discharges for up to 2 weeks, and it is present in goat milk for up to 52 days after kidding and also in feces. Maximum shedding in cattle also occurs at parturition and for the following two weeks but cattle excrete the organism in the milk for at least several months and up to 2 years and infection is common in bulk tank milk. As with sheep, infection in goats can be accompanied by abortion but abortion in cattle is rare although it is recorded. 

There is a significant contamination of the environment of infected animals at the time of parturition and this is probably a major period for transmission of the disease within herds and flocks. The organism is present in the semen of seropositive bulls and venereal transmission is suspected.

Pathogen risk factors

C. burnetii is very resistant to physical and chemical influences and can survive in the environment and soil for several months. It can resist common chemical disinfectants but is susceptible to sodium hypochlorite, 1:100 lysol solution and formalin fumigation provided a high humidity is maintained.

There is strain variation in the organism and differences in plasmid sequence types have been correlated with differences in the type of disease occurring in humans. The organism is highly infectious and it is estimated that the infective dose for humans approximates one organism.

Zoonotic implications

In humans infection is primarily by inhalation. Sources of infection include such diverse materials as soil, air-borne dust, wool, bedding and other materials contaminated by urine, feces or birth products of animals. The potential for human infection from these sources is substantial; for example, ovine manure used as a garden fertilizer has been incriminated as a source.

Sheep have traditionally been incriminated as the major reservoir of infection for humans but the trend for urban populations to locate in close proximity to large dairy herds suggests that cattle could become an increasingly significant reservoir. The organism is present in the milk of infected cattle, sheep and goats. A significant proportion of seropositive cattle excrete the organism in milk and periods and duration of excretion are variable but may persist at least 2 years. C. burnetii is destroyed by pasteurization but there is a risk for the farm family that consumes raw milk and a particular concern for the occurrence of the organism in raw sheep and goats' milk.

Rates of seropositivity in humans vary markedly between surveys but there is a higher rate of seropositivity in people (farm workers, veterinarians, livestock dealers, dairy plant and slaughter house workers, shearers, etc.) that are associated with...
domestic animals and their products and with farm environments. Several incidents of infection in humans have been linked to exposure to parturient sheep and goats. The infection in humans is also commonly asymptomatic but can result in disease characterized by fever, general malaise, headache, and less commonly, pneumonitis, hepatitis and meningocoeptalitis. Endocarditis and hepatitis are manifestations of chronic disease. Immunocompromised persons are at greater risk for disease. A subsequent greater risk for infection in farm animals is increasing and spreading geographically and that there is a subsequent greater risk for infection in humans.

C. burnetii is considered a potential agent for bioterrorism because of its survival in the environment, the ease with which it can transmit by aerosol and windborne means and the very low infectious dose.

CLINICAL FINDINGS
Infection of ruminants can occur at any age and is usually clinically inapparent. In the experimental disease in cattle, anorexia is the only consistent clinical finding. C. burnetii is a cause of abortion in sheep and goats. Abortion occurs during the latter part of the lambing period in the flock and in the latter period of pregnancy in individual ewes. The dam shows no signs of impending abortion. In cattle the organism is a rare cause of abortion. Correlations between herd level seroprevalence and herd fertility are equivocal.

CLINICAL PATHOLOGY
There are a number of serological tests available including complement fixation, micro agglutination, ELISA and indirect immunofluorescence. The immunofluorescence assay is used as the sero-reference test for the serodiagnosis of Q fever. It can detect antibody to phase variants and can provide epidemiological information as phase II antibody is associated with recent and acute infections and phase II antibody with chronic infections.

NECROPSY FINDINGS
There are seldom gross lesions in aborted fetuses, but foci of necrosis and inflammation are occasionally seen in the liver, lung, and kidney microscopically. The placenta from aborting animals is usually thickened and a purulent exudate or large, red-brown foci of necrosis are typically seen in the thickened intercotyledonal areas. Microscopically, large numbers of necrotic neutrophils are usually visible on the chorionic surface and swollen trophoblasts filled with the organisms can also be found in well-preserved specimens. Examination of placental impression smears stained with Gimenez, Koster’s, or other appropriate techniques provides a means of rapid diagnosis. However, care must be taken to avoid confusing Coxiella-infected trophoblasts with cells containing Chlamydiae organisms. Coxiellosis can be confirmed fluorescent antibody staining of fresh tissue or immunohistochemical staining of formalin-fixed samples. In most laboratories, culture is not attempted due to the zoonotic potential of this agent.

Samples for confirmation of diagnosis
- Bacteriology – chilled placenta (CYTO, FAT)
- Histology – fixed placenta, lung, liver, kidney (LM, IHC)

Note the zoonotic potential of this agent when handling carcasses and submitting specimens.

DIFFERENTIAL DIAGNOSIS
- The diagnosis of the disease in farm animals, other than abortion, suspected as associated with this agent is difficult and relies upon the detection of the organism
- A positive serological test in an animal or herd is indicative of infection at some time but does not indicate an association with the problem at hand
- PCR or PCR-ELISA has been used for detection of the organism in milk

CONTROL
Aborting animals should be isolated for 3 weeks and aborted and placental-contaminated material burnt. Ideally, manure should be composted for 6 months before application to fields. Feed areas should be raised to keep them free from contamination with feces and urine. While Q fever has significant implications for human health, it is not significantly important enough to have generated national or regional control strategies based on control in the animal population.

Milk and milk products should be pasteurized. Veterinarians dealing with herds that provide raw milk should insure that these herds are seronegative for C. burnetii.

Vaccine trials with killed vaccines in animals show a good and persistent antibody response and suggest that vaccination can limit the excretion of the organism. However, there is little economic incentive for a vaccination program involving livestock and livestock vaccines are not available in most countries.

Vaccination of humans has reduced infection rates in high risk groups and has been used in the appropriate circumstances in Australia. As defined by recognized infections, personnel in research facilities that contain sheep are at greatest risk for infection and management guidelines for the control of Q fever in research facilities containing agricultural animals are available.

REFERENCES

BOVINE PETECHIAL FEVER (ONDIRI DISEASE)
Bovine petechial fever is associated with Ehrlichia odiri and occurs in Kenya, and possibly Tanzania, in cattle grazing thick scrub land or indigenous forest areas at 1500–3000 m altitudes. Characteristically, disease occurs in cattle that break out from fenced pastures and graze the adjacent forest or bushland areas, or when they are grazed on these areas at the end of the dry season. Bovine petechial fever occurs in cattle that have recently introduced to these areas and indigenous cattle appear to acquire resistance. Epidemics occur in cattle imported to infected areas, last
1–2 months to involve 60–80% of the group with significant losses. Dairy cattle have significant drop in milk yield which persists for several weeks.\textsuperscript{1}

Infection can be \textbf{experimentally transmitted} to cattle, sheep, goats, wildebeest and impala but natural disease is seen only in cattle.\textsuperscript{1,2} Bushbuck (\textit{Tragelaphus scriptus}) are suspected as the reservoir for infection but the vector is not known although epidemiological findings suggest a tick vector of restricted distribution.\textsuperscript{3}

The \textbf{disease in cattle} is characterized by high fever and the occurrence of petechial hemorrhages in mucous membranes for periods up to 10 days; epistaxis, melena, and hyphema occur in more severely affected animals. Pregnant animals may abort and there is a fall in milk production in lactating animals. Anemia may be severe enough to result in death 3–4 weeks after infection.\textsuperscript{1} There is a profound lymphocytopenia by the second day of infection followed by leukopenia and thrombocytopenia. The organism is demonstrable in granulocytes and monocytes during the febrile period but cannot be cultured.

Tetracyclines are effective in treatment. Recovered animals may be latently infected and are immune to reinfection for at least 2 years.

**Algal diseases**

**ALGAL BACTEREMIA**
- Asymptomatic systemic infections and lymphadenitis associated with the algae *Prototheca zopfii* are extremely rare in cattle and sheep. More common are mastitis and poisoning by algae.

**PROTOTHECOSIS**
- Protothecosis is associated with a species of algae belonging to the genus *Prototheca.*
- *Prototheca wickerhammii* and *P. zopfii* are the only species reported to be pathogenic for animals and man. Single cases have been reported in deer and cats, a few in dogs, and numerous cases in cattle. In cows, all infections have been restricted to the mammary glands and corresponding localizations. 1 Peracute, septicemic infections are very rare in adults, except in the occasional case in a parturient female, but are not infrequent in newborn calves and foals.

**REFERENCES**

**Fungal diseases**

**DERMATOMYCOSIS 1476**
- Bovine mastitis, usually a sequel to intramammary medication with a contaminated infusion, is a constant occurrence.
- Fungi also appear in the lists of causes of many diseases associated with mixed infections such as neonatal septicemia, enterocolitis, endocarditis, pneumonia and lymph node abscessation.

**ASPERGILLOSIS, CANDIDIASIS, ZYGOMYCOSIS, AND MALASSEZIOSIS**
- Mycoses including aspergillosis, candidiasis and zygomycosis in animals are usually sporadic infections and cause non-specific syndromes because of variation in the organs in which they localize. 1 Peracute, septicemic infections are very rare in adults, except in the occasional case in a parturient female, but are not infrequent in newborn calves and foals.

**ETIOLOGY**
- *Aspergillus* and *Candida* spp., and the zygomycoses *Absidia corymbifera, Rhizopus oryzae, Rhizomucor (Mucor) pusillus* and *Mortierella wolfii* are the common infections which cause systemic mycotic disease. Rare infections occur with *Scopulariopsis* spp. The infections most commonly recorded in bovine mycotic abortion are *Mucor, Aspergillus* spp., *Petriellidium (Allescheria) boydii, Candida parapsilosis* and *Mortierella wolfii."

**YEASTS OF THE GENUS MALASEZIA**
- Yeasts of the genus *Malassezia* inhabit the skin of a variety of mammals and birds and are considered as opportunistic pathogens in animals and man. 1 In a survey of a sample of domestic animals in Spain, *Malassezia* spp. were isolated from 60% of horses, 28% of sheep, 44% of goats, and 58% of cows. The species isolated included: *M. sympodialis, M. globosa and M. restricta* from sheep. *M. pachydermatis, M. furfur, M. sympodialis, M. obtusa, M. globosa, and M. restricta* from goats and *M. furfur, M. slooffiae, M. obtusa, M. globosa* and *M. restricta* from horses.

- Many different species of fungi have been isolated from the conjunctival sac of horses, including *Aspergillus* spp., and other molds such as *Cladosporium, Mucor, Fusarium, Alternaria,* and *Candida* spp.

**EPIDEMIOLOGY**
- This is distinctive in fungal diseases; they are not contagious with the exception of maternal infections which cause the disease in their calves. Each infection arises from the fungal habitat as a saprophyte in organic matter, commonly moldy hay or straw or moist feeds such as beet pulp or brewers' grains which are allowed to go moldy. Risk factors thought to increase the prevalence of oral–gastric mycosis in young pigs and calves are continued and heavy oral dosing with antibiotics and feeding on poorly formulated or administered artificial diets. *Candida glabrata* may have been associated with fungal gastritis and ulcerative colitis in a foal treated with rifampin and spiramycin for rhodococcal bronchopneumonia.

- An outbreak of neurological disease in dairy cattle associated with consumption of beer residues contaminated with *Aspergillus clavatus* has been described in Brazil. Beer residues from malting and brewing factories are widely used for dairy cattle feeding in southern Brazil. The affected farm had been feeding beer residues successfully for 15 years.

- Fecal samples and intestinal contents of preweaned dairy calves contain yeasts, among which *Candida glabrata* is most common and may be associated with some cases of diarrhea. Feeding calves their dam's milk reduced the shedding of the yeasts compared to commercial milk replacer.

- The incidence of mycotic abortions is much greater (up to 30% of all abortions in the herd) in the winter months in housed cows than in any other group,
probably because they are exposed to an environment which is likely to be heavily contaminated with spores from moldy hay and ensilage. A correlation also occurs between the abortion rate and a high rainfall in the haymaking season prior to conception.

The increasing incidence of mycotic placental inflammation leading to abortion may be related to the general use of antibiotic-treated semen in artificial insemination programs but the incidence is no higher in artificially bred cows than in those mated naturally. It is more likely that a transient systemic infection is followed by localization in the pregnant uterus causing placentalitis and abortion. In humans there is an increasing prevalence of systemic mycoses because of the increasing frequency of immunodeficiency states, but prolonged and intensive antibiotic therapy is a commoner precursor in farm animals, especially in aspergillosis.

Microbiological investigations of the guttural pouch of horses affected with mycotic infections have frequently demonstrated the presence of several different *Aspergillus* spp. *Candida krusei* has been isolated from a case of bronchopneumonia in one-year old heifer which was incurable and had to be euthanized. Fungal keratitis (keratomycosis) in horses has been regarded as rare but now account for about 30% of horses diagnosed with keratitis. In the northern hemisphere the disease is more common in the summer and autumn, possibly because climatic and environmental factors favor the proliferation of fungal spores.

Human zygomycosis has been on the increase, and this trend is expected to continue due to increases in the number of immunocompromised hosts. The literature on the animal models of *Zygomycosis-Absidia, Rhizopus, Rhizomucor, and Cunninghamella* has been reviewed. Zygomycetes are filamentous fungi which are natural inhabitants of soil and fairly common in the environment. They comprise Mucorales and Entomophthorales.

Mucormycosis due to *Absidia cordyembena* has been described occurring in ponies and 4 of 15 animals died within a few days of onset.

**PATHOGENESIS**

Although inhalation of dust containing fungal elements is an obvious portal of entry for the fungi, with a primary focus developing in a lung, it is generally believed that the more common portal is in the alimentary tract, where the mycoses establishes in a pre-existing abomasal or gastric ulcer or is established in the normal lining of the forestomachs, abomasum and intestines. Hematogenous spread from these foci occurs to all organs, especially splanchic lymph nodes, liver, lungs and the placenta in pregnant females. Only the placenta is invaded and subsequent fertility is not impaired. Infection of the placenta and uterus can be established by intravenous injection during pregnancy but not by of the injected animals develop placentalitis and granulomas in the liver and lungs, and this proportion can be increased by increasing the dose of spores injected.

In *keratomycosis* in horses, traumatic injury to the cornea by plant material, the prolonged use of topical antibiotics may cause a shift in the normal conjunctival flora from Gram-positive to Gram-negative organisms, and the use of topical corticosteroids can all contribute to fungal growth. In temperate climates keratomycosis is normally a chronic disease associated with ocular trauma. Small corneal ulcers may heal, trapping the organisms deep within the stroma, and result in the development of a stromal abscess. Large stromal ulcers may fail to heal and be slowly progressive, and the corneal stroma may melt. Various categories of stromal ulcers occur including: superficial fungal keratitis (punctate lesions of the epithelium and sub-epithelium stroma); keratomycosis with a surrounding furrow; keratomycosis with a ‘cake frosting’ appearance; and stromal abscesses.

Neurological disease in cattle associated with the consumption of beer residues contaminated with *Aspergillus clavatus* is due to the neuromycotoxicosis effect of the mycotoxins of the fungi. Additional information is available in the chapter dealing with mycotoxicoses.

**CLINICAL FINDINGS**

**Pneumonia**

Mycotic pneumonia is uncommon in farm animals but occasional cases or outbreaks occur in all species, sometimes with generalization. A high prevalence can be expected in calves and lambs kept indoors in intensive housing units. The pneumonia may be chronic, subacute or acute – a fibrinous pneumonia of very short duration. All forms are fatal and are characterized by mouth-breathing dyspnea, profuse salivation and a mucopurulent nasal discharge and accompanying crustating and erosion. Vescication or ulceration of the muzzle, profuse lacrimation. There is corneal ulceration with or without furrowing, or stromal abscessation. The duration is commonly several weeks even with treatment. The differential diagnosis of infectious ulcerative keratitis includes: recurrent uveitis, bacterial or viral ulcerative keratitis, stromal abscesses associated with fungi or bacteria.

**Encephalopathy**

An outbreak of encephalopathy has been described in dairy cattle fed beer residue contaminated with *Aspergillus clavatus*. Clinically affected cattle by flaccid paralysis and gait abnormalities. Clinical signs were more pronounced after exercise and included stiff and unsteady gait, knuckling of the fetlocks of the hindlimbs, frequent falling, inability to rise, muscular tremors especially of the head and hind-quarters, and drooling. The clinical course varied from 2 days to 2 weeks, most animals died or were euthanized, the population mortality rate of herd was 15%. New cases stopped after the feeding of beer residue was discontinued.

**Guttural pouch disease of horses**

Guttural pouch disease affects mature horses but it may occur in animals as young as 6 to 12 months of age. The most common clinical findings are mucopurulent nasal discharge (unilateral or bilateral), dysphagia, Horner’s syndrome, laryngeal hemiplegia or atrophy of the tongue. The diagnosis is made with endoscopy and biopsies may be taken for histological examination and fungal culture.

**Keratomycosis in horses**

Fungal keratitis is normally very painful with marked corneal change accompanied by a severe uveitis, blepharospasm, photophobia and lacrimation. There is corneal ulceration with a ‘cake frosting’ appearance, ulceration with or without furrowing, or stromal abscessation. The duration is commonly several weeks even with treatment. The differential diagnosis of infectious ulcerative keratitis includes: recurrent uveitis, bacterial or viral ulcerative keratitis, stromal abscesses associated with fungi or bacteria.

**Pharyngitis/gastroenteritis**

Mycotic pharyngitis and gastroenteritis in pigs and calves results in diarrhea and, in pigs, vomiting. There is commonly a white pseudomembrane at the back of the pharynx and extending down the esophagus to the stomach. Cases of mycotic enteritis, ranitis and enteritis in adult ruminants show anorexia, fever and diarrhea. Mycotic enteritis secondary to carbohydrate engagement is a separate issue dealt with elsewhere.
Abortion
Fungal placentitis resulting in abortion occurs in cows usually at months 6-8 of their pregnancy. Placental lesions are described below and hyphae can be seen on examination of direct smears of the cotyledon or the fetal stomach, preferably the former. A dermatomycosis occurs rarely in the aborted fetal calves, with discrete patches of alopecia, and a raised, grayish, felted covering occurring all over the body. Congenital infection may also occur, granulomatous lesions containing the fungus may be found in the lungs of day-old lambs.

Mammary aspergillosis
Aspergillus mastitis, associated with Aspergillus fumigatus, occurs in ewes causing a severe infection resulting in destruction of the infected mammary tissue.

Other manifestations
- **Preputial catarrh** accompanied by slowness of service and masturbation has been associated with infection in bulls by an Absidia sp. fungus thought to be transmitted at coitus.
- **Dermatitis** associated with Candida spp. can occur in pigs kept in a damp environment.
- **Cutaneous mycotic granulomata,** causing lesions similar to those of cutaneous tuberculosis, occurs rarely in cattle.
- **Intramammary Aspergillus fumigatus** infection in dairy ewes has been associated with antibiotic dry therapy.
- Severe debilitating mastitis was observed and it contamination of the teat ends at the time of administration of the antibiotic was suspected.

CLINICAL PATHOLOGY
Sophisticated laboratory techniques are now available to diagnose systemic mycoses and to identify the pathogen. These include immunostaining of tissues and serological methods. All of the following techniques have been used but there is no clearly defined, superior set of tests:
- Polymerase chain reaction
- Murine monoclonal and rabbit polyclonal antibodies in histochemistry
- Immunoblotting
- ELISA of antibodies in serology.

In ewes with Aspergillus mastitis, the detection of antibody by ELISA in sera is a reliable method for the diagnosis.

In mycotic pneumonia, radiodense areas in the lung, representing typical granulomata, are characteristic and transcranial washes contain many fungal bodies.

In keratomycosis in horses, samples must be taken from the lesions and submitted for culture of fungi on Sabouraud’s agar. Deep corneal biopsies may be necessary to confirm the diagnosis.

NECROPSY FINDINGS
*Alimentary tract*
Lesions in pigs are edema, hemorrhage, and ulceration of the gastric (or abomasal in the case of calves), intestinal and sometimes the esophageal mucosa. Lesions of the forestomachs in adult ruminants include acute hemorrhagic mucosal necrosis.

*Encephalopathy and myopathy*
In cattle affected with Aspergillus clavatus in beer residue, gross lesions consisted of degeneration and necrosis of large muscle groups of the hindquarters. Histologically, there was degeneration and necrotic neuronal changes in the brainstem and neurons of the ventral horns of the spinal cord.

*Respiratory tract*
Lesions include severe fibrinous pneumonia in very acute cases, and multiple discrete granulomata, often appearing as small abscesses, often with necrotic centers giving a superficial resemblance to tuberculosis in the lungs. In lambs the granulomata appear as very small nodules (1-3 mm diameter) and resemble those associated with infestation with Muelleria capillaris.

In mycotic pneumonia in a cow associated with Mortierella wolfii, the lung was firm, dark red, had bilateral adhesions between the caudal aspects of the lungs and the diaphragm. Histologically, there is severe acute fibrinous broncho-pneumonia with multifocal necrosis. Large numbers of non-septate, non-dichotomous, irregular branching hyphae are present in the alveoli.

*Lymph node granulomata*
These are a common finding, often in normal animals on the slaughter floor and seen in the mesenteric, mediastinal and submandibular lymph nodes. These are of importance in the differential diagnosis of tuberculosis.

*Reproductive tract*
Placentitis characterized by necrosis of the maternal cotyledons, the adherent necrotic material giving the placental cotyledon the appearance of a soft, yellow, cushion-like structure, and small yellow, raised leathery lesions on the intercotyledonary areas are diagnostic. Corresponding lesions occur on the endometrium, and ringworm-like lesions occur on the fetal skin. Hyphae can be seen on examination of direct smears of cotyledons, fetal stomach and skin. If mycotic abortion is suspected the placental cotyledons offer the best source of material. Every effort should be made to obtain the entire placenta as the infection may be patchy and involve only a few cotyledons. The fungi can be cultured on suitable media.

Equine mucormycosis
Systemic mucormycosis in a horse due to Absidia corymbifera has been described. Pulmonary congestion, pleural hemorrhages and a brain infarct were present.

TREATMENT
Treatment of systemic mycoses has been largely by amphotericin and nystatin but the newer azole compounds (itraconazole, fluconazole, itraconazole, ketoconazole) administered orally appear to be highly effective and easy to administer. Any attempt at control of systemic fungal infections is disadvantaged by the lack of a reliable typing system for the causative fungi.

The treatment of keratomycosis in horses is a special topic and the reader should consult the literature in veterinary ophthalmology. Treatment consists of topical antifungal agents, systemic non-steroidal anti-inflammatory agents to control ocular pain, the placement of a lavage system for the regular administration of drugs into the eye, and a consideration of keratectomy and conjunctival graft as necessary.

REVIEW LITERATURE

REFERENCES
ASPERGILLOSIS IN HORSES (ASPERGILLUS SPP)

Diseases of horses associated with infection with Aspergillus spp. are characterized by either localized infections with slow progression or fulminant systemic or pulmonary disease. Localized infections are of the nasal cavities and paranasal sinuses, eye, reproductive tract including placenta, mediastinum, or guttural pouch. Systemic disease can affect any organ, including brain, liver and kidney, but the most common manifestation is as acute pulmonary disease with or without infection of other tissues.

The causative organism is Aspergillus spp. usually A. fumigatus but occasionally one of A. flavus, A. restrictus, A. nidulans, A. niger or A. clavatus. Aspergillus reproduce both sexually and asexually and hence are classified as dimorphic fungi. Asexual reproduction is by production of conidiophores and conidia. The organism is ubiquitous in organic material and infections are opportunistic and associated with heavy contamination with the organism or decreased host defenses, although obvious risk factors are not always identified. Because its ubiquitous, the organism is often recovered from tracheal aspirates performed using contaminated equipment in horses with mild signs suggestive of non-infectious respiratory disease, such as heaves. In this instance recovery of the organism is of no clinical importance.

Risk factors for development of aspergillosis include heavy contamination with conidia, and decreased host resistance, such as in horses with immune suppression associated with myeloproliferative disease (lymphoma), enterocolitis, and administration of immunosuppressive drugs such as corticosteroids. Specific risk factors for guttural pouch mycosis and infections of the nasal cavity or paranasal sinuses have not been identified with the exception of an association between surgical resection of ethmoidal hemotoma and subsequent nasal aspergillosis. Keratomycosis associated with Aspergillus spp. is usually secondary to other ocular lesions, or ocular instillation of immunosuppressive drugs. The ocular disease can also occur in horses housed in barns with heavy contamination with Aspergillus spp. Systemic or pulmonary aspergillosis is commonly associated with enterocolitis or administration of immunosuppressive drugs in adult horses.

Aspergillus spp. causes both localized and systemic disease in horses. Localized diseases include guttural pouch mycosis, which is discussed in detail elsewhere in this text. Fungal granulomas in the paranasal sinuses or nasal passages of horses are caused by a number of organisms, including Cryptococcus neoformans, and rarely by Aspergillus spp. The disease is evident as nasal discharge that is usually unilateral, distortion of the contour of the head over the affected sinus, and lesions detectable on endoscopic examination of the nasal passages. Radiography can reveal the presence of a mass in the paranasal sinuses or nasal cavity associated with lysis and proliferation of bone. There is hyperfibrinogenemia and leukocytosis.

Keratomycosis due to Aspergillus spp. infection is infrequent in horses. The disease is characterized by blepharospasm, photophobia, epiphora, and corneal ulceration and opacity. Aspergillus spp. infections of the reproductive tract include mycotic placentalitis and abortion and mycotic endometritis.

Systemic aspergillosis, including aspergillus pneumonia, is a severe disease usually evident as acute death without localizing signs in horses with other preexisting systemic disease, such as enterocolitis, or those receiving immunosuppressive drugs. Horses with aspergillus pneumonia often have a very brief clinical course once signs of respiratory disease develop. Most commonly, horses with pulmonary aspergillosis die without signs of respiratory disease. Signs of pulmonary aspergillosis include fever, tachypnea, crackles and wheezes on thoracic auscultation, epistaxis, and frothy nasal discharge. Radiography reveals diffuse, miliary, nodule interstitial pneumonia. Ultrasonographic examination demonstrates numerous small intrapulmonary masses adjacent to the pleural surface. Affected horses have hyperfibrinogenemia and leukocytosis at the time of development of the disease, but usually have had neutropenia as a result of the enterocolitis. Aspergillus spp. can be isolated from tracheal aspirates of affected horses. The prognosis is very poor.

Disseminated aspergillosis has a variety of manifestations but is always a severe disease with a brief clinical course. Affected horses often have severe depression and can have signs of brain disease as a result of mycotic vasculitis and encephalitis. The prognosis is very poor.

Aspergillus spp. is also associated with development of granulomas in the mediastinum of horses without apparent predisposing factors. Affected horses have progressively worsening respiratory distress, cough, fever, and occasional nasal discharge. Horner's syndrome can develop if the mass encroaches on the vagosympathetic trunk within the thorax. The mass is evident on radiographic examination of the thorax. Cultures of tracheal aspirates yields Aspergillus spp. Affected horses have neutrophilia, hyperfibrinogenemia, hyperglobulinemia and mild anemia.

Definitive diagnosis of the disease is based on demonstration of organisms within lesions, either by histologic examination or by culture, and by demonstration of high titers in serum of antibodies specific for Aspergillus spp. Antemortem demonstration of high concentrations of antibodies to Aspergillus spp. provides persuasive, but not definitive, evidence of infection. Both agar gel immunodiffusion assays and ELISA assays are available. These assays might not be useful in immunocompromised animals or in those with fulminant disease.

Acute lesions are characterized by purulent, necrotizing inflammation. Chronic lesions are granulomas that contain macrophages, neutrophils and giant cells. Pulmonary lesions are characterized by an acute necrohemorrhagic alveolitis. Organisms morphologically consistent with Aspergillus spp. are detected in the lesions as fungal hyphae, although these must be differentiated from Pseudoallescheria boydii or Fusarium spp. Reagents for immuno-fluorescent detection of Aspergillus spp. in lesions are available and useful in confirming the diagnosis.

Treatment of systemic or pulmonary disease is usually unrewarding. Localized disease can be treated by surgical resection and administration of antifungal agents. Antifungal agents reported to be effective in treatment of localized disease associated with Aspergillus spp. include itraconazole (3 mg/kg q 12 h, PO for 3–5 months). Topical treatment with enilconazole (10 mg/mL of solution) after surgical resection resulted in resolution of aspergillosis of the frontal sinus of a horse. Topical administration of natamycin (25 mg) was used for varying periods of time to treat mycotic rhinitis in three horses.

Amphotericin is likely effective against Aspergillus spp. and is cheaper than the azole class of drugs, but is potentially nephrotoxic and must be administered intravenously. Fluconazole is not effective against the filamentous fungi, including Aspergillus spp.

There are no specific control measures or means of preventing disease associated with Aspergillus spp.

REVIEW LITERATURE
Coccidiodomycosis

**ETIOLOGY**
Coccidioides immitis is associated with the disease in all species including humans.

**EPIDEMIOLOGY**
Coccidioidomycosis is a comparatively benign disease of farm animals, usually causing no apparent illness. Sporadic cases are recorded in all species but are most common in dogs and in cattle and to a much less extent in pigs, sheep, and horses. Pulmonary coccidioidomycosis has been described in a 13-day-old foal.

The disease is enzootic in the southwestern United States and up to 20% of cattle finished in feedlots in the area may harbor the fungus. The incidence of the disease in humans in the area provides a major problem in public health. It is not contagious, infection occurring by inhalation of spores of the fungus which grows in the soil, and possibly by ingestion and through cutaneous abrasions.

**CLINICAL FINDINGS**
In horses findings include weight loss up to severe emaciation, a fluctuating temperature, persistent cough, muscle pain, and superficial abscesses, often recurring, and most commonly in the pectoral area. Increased lung sounds, wheezing, and dullness are audible over the ventral chest. Other signs include edema of the legs, anemia and intermitent colic due to internal abscesses and peritoneal adhesions. Liver rupture may cause death. Affected sheep show fever and abscesses in peripheral lymph nodes.

**CLINICAL PATHOLOGY**
A leukocytosis is usual. An extract of the fungus, coccidioidin, has been used in an intradermal sensitivity test, and complement fixation and immunodiffusion tests are used diagnostically in humans.

**NECROPSY FINDINGS**
The lesions produced in cattle and pigs are granulomatous, contain a cream-colored pus, and are sometimes calcified and are found in the bronchial, mediastinal and rarely the mesenteric, pharyngeal and submaxillary lymph nodes and in the lungs. In a neonatal foal, the lungs were diffusely infiltrated with a miliary pattern of multiple, coalescing, pale tan to red, irregularly shaped, slightly raised, firm foci, 0.1 to 0.5 cm in diameter.

**DIFFERENTIAL DIAGNOSIS**
Microscopic or cultural examination may be used to identify the disease. Isolation of the organism is preferred as evidence because of the non-specificity of coccidioides.

**DIFFERENTIAL DIAGNOSIS LIST:***
- Cattle and pigs – tuberculosis
- Sheep and goats – caseous lymphadenitis.

**REFERENCES**

Rhinosporidiosis

Rhinosporidiosis is a chronic disease of the nasal mucosa in cattle and horses causing formation of large polyps in the posterior nares and interference with respiration. The causative fungus, Rhinosporidium seeberi, can be found in large sporangia in the polyps.

A related condition in cattle also thought to be caused by an unidentified fungus, similar to Rhinosporidium spp., is nasal granuloma, in which the lesions are small (0.5–2.0 cm diameter) mucosal nodules in the anterior third of the nasal cavity. Histologically there is a marked eosinophilic reaction and yeast-like bodies are present in cells or free in the tissue spaces. Clinical signs include severe dyspnea with loud stertor and a mucopurulent or blood-stained nasal discharge. A high incidence of the disease may occur on some farms and in particular areas.

Other diseases with similar clinical profiles include nasal obstruction associated with the blood fluke, Schistosoma nasalis and chronic allergic rhinitis.

**REFERENCES**

**HISTOPLASMOSIS**

Histoplasmosis, associated with infection with *Histoplasma capsulatum*, is a rare systemic mycosis in farm animals, with a high prevalence in specific geographic localities, e.g. the Mississippi river system. Cases have been recorded in horses, cattle and pigs. The fungus is able to survive for periods as long as 4 months in soil and water. Infection occurs by the inhalation of contaminated dust, and primary invasion usually takes place in the lung. The disease may spread from animals to humans. Attempts at experimental infection in cattle, sheep, horses and pigs have resulted in non-fatal infections, unless the agent is given intravenously, but the test animals become positive to the histoplasm cutaneous sensitivity test.

Clinical syndromes vary greatly and include pneumonia, with dyspnea and nasal discharge, hepatic insufficiency with jaundice and anasarca, placentitis with abortion, and widespread lesions in neonates, especially foals. As a diagnostic aid for herd or area the histoplasmin skin test appears to be satisfactory. Keratitis due to *Histoplasma* spp. has been described. Histoplasmosis may be secondary to *Yersinia* in the horse.

Necropsy lesions are as variable as the clinical syndrome and include gross hepatic enlargement containing necrotic foci, pulmonary consolidation and granulomatous pneumonia, and enlargement of splanchic lymph nodes. Aggregation of the fungal bodies in lymphoid tissue and other tissues in which large numbers of phagocytes are in residence is characteristic of the disease; the lesions consist of groups of macrophages packed with fungal cells.

The disease associated with infection with *H. farricinosum* is dealt with under the heading of epizootic lymphangitis.

**REFERENCES**
The fungus associated with this important mastitis. In human medicine an accurate serological test is used in diagnosis.

**NORTH AMERICAN BLASTOMYCOSIS**

The fungus associated with this important zoonosis is *Blastomyces dermatitidis*. It is relatively common in dogs but appears to have been recorded only once in large animals causing perineal abscessation, emaciation and death in a horse. In humans and dogs the characteristic lesions are cutaneous or pulmonary granuloma.

<thead>
<tr>
<th>Synopsis</th>
</tr>
</thead>
<tbody>
<tr>
<td>Invasion of cutaneous keratinized epithelial cells and hair fibers by dermatophytes.</td>
</tr>
</tbody>
</table>

**Etiology** *Trichophyton*, *Microsporum* spp., fungi

**Epidemiology** Carrier animals are the source; spread is via direct contact or contact with infected inanimate objects. Housed animals most susceptible

**Clinical signs** Circumscribed areas of hairless skin, thick gray crumbly crusts (cattle), or shiny, bald areas (horse), heavy ptyriasis; common locations where infection likely to contact e.g. neck, sides

**Clinical pathology** Spores and mycelia in skin scraping, or in culture

**Necropsy lesions** Mycelia identifiable in skin sections

**Diagnostic confirmation** Lab typing of fungus in scraping or tissue

**Treatment** Spontaneous recovery usual.

**EPIDEMIOLOGY**

**Occurrence, source of infection and transmission**

Ringworm occurs in all animal species in all countries but more commonly where animals are accommodated in dense groups, especially indoors.

Direct contact with infected animals is the common method of spread of ringworm, but indirect contact with inanimate objects, particularly bedding, harness, grooming kits and horse blankets, is probably more important. Spores can exist on the skin without causing lesions, and up to 20% of normal animals in an infected group will act as ‘carrier animals’.

Premises and harness may remain infective for long periods because fungal spores remain viable for years provided they are kept dry and cool. Moderate heat and desiccation destroy them.

A dermatophytosis in lambs in the United States, called ‘club lamb fungus’ affects lambs during lamb show season. Approximately one-third of families reported children or owners involved in showing these lambs developed skin lesions consistent with dermatophytosis.

Ringworm in yearling horses can interfere with training causing economic losses because of the isolation required to prevent spread of infection to other horses and humans and to decrease environmental contamination.

**Risk factors**

Pathogen factors

*Trichophyton*, *Microsporum* and *M. nanum* are soil saprophytes and the reasons for their assumption of pathogenicity are not understood.

**Environment and host factors**

A high incidence of clinical cases in the winter and of spontaneous recovery in the spring is common, but outbreaks also occur during the summer months, so that close confinement and possibly nutrition seem to be more important in the spread of the disease than other environmental factors such as temperature and sunlight. Humidity is known to be important, a high humidity being conducive to multiplication of the fungus. In calf-rearing and vealing units the prevalence is greater in units which continuously add or remove calves from the stock; an `all-in all-out' program is less conducive to spread of the disease.

Animal susceptibility is determined largely by immunological status, so that young animals are most susceptible.

**Zoonotic considerations and economic importance**

Spread between species occurs readily and in rural areas 80% of human ringworm may derive from animals. *Trichophyton* spp. infections are commonly contracted from horses and cattle and *M. canis* infections from dogs. Ringworm of animal origin affects adult humans as well as children and diagnosis and treatment are often very difficult. Between 1962 and 1994, 32 isolates of *Trichophyton verrucosum* from cases tinea corporis, tinea faciei and tinea capitis were identified in Victoria, Australia. Infected patients were mainly from farm areas and frequently had a history of contact with cattle. Isolates included those from dairy and beef cattle farmers, children who lived on dairy or cattle farms or in a dairy farming area, a slaughterhouse employee and a veterinarian.

Injury to affected animals is of a minor nature but sufficient damage to hides occurs to warrant some attempt at control of the disease.

**PATHOGENESIS**

Ringworm fungi chiefly attack keratinized tissues, particularly the stratum corneum and hair fibers, resulting in autolysis of the fiber structure, breaking off of the hair, and alopecia. Exudation from invaded epithelial layers, epithelial debris and fungal hyphae produce the dry crusts which are characteristic of the disease. The lesions progress if suitable environmental conditions for mycelial growth exist, including a warm humid atmosphere, and a slightly alkaline pH of the skin. Ringworm fungi are all strict aerobes and the fungi die out under the crust in the center of most lesions, leaving only the periphery active. It is this mode of growth which produces the centrifugal progression and the characteristic ring form of the lesions.
The significance of skin pH in the development of ringworm is widely known. The susceptibility of humans to ringworm infection is much greater before puberty than after puberty when the skin pH falls from about 6.5 to about 4.0. This change is largely due to excretion of fatty acids in the sebaceous and these fatty acids are often highly fungistatic. Calves are more commonly infected than adult cattle but whether this is due to increased susceptibility in calves or the development of immunity in adults has not been determined.

There is some experimental evidence that traumatic injury of the skin is an important factor for the development of ringworm lesions in calves. Different numbers of microconidia of Trichophyton verrucosum are required to induce ringworm depending on the degree of shearing of the hair and scarring of the skin.

Secondary bacterial invasion of hair follicles is common. The period after experimental infection before distinct lesions appear is about 4 weeks in calves, but considerably less in horses. Spontaneous recovery occurs in calves in 2-4 months, the duration and severity of the disease often depending upon the nutritional status of the host. A resistance to reinfection occurs after recovery from experimental or natural infection even though a local mycotic dermatitis may occur at the reinfection site. The immunity is specific to the fungal species concerned, and in horses lasts up to 2 years.

**CLINICAL FINDINGS**

**Cattle**

The typical lesion is a heavy, gray-white crust raised perceptibly above the skin. The lesions are roughly circular and about 3 cm in diameter. In the early stages the surface below the crust is moist, in older lesions the scab becomes detached and ptyriasis and alopecia may be the only obvious abnormalities. Lesions are most commonly found on the neck, head and perineum but a general distribution over the entire body may occur, particularly in calves, and in severe cases the lesions may coalesce. Itching does not occur and secondary acne is unusual.

**Horses**

The lesions may be superficial or deep. Superficial infections are more common. Lesions due to Trichophyton equinum commence as round patches of raised hair and sourness of the lesions to touch. This stage is followed about 7 days later by matting of the hair, which becomes detached leaving a bald, gray, shining area about 3 cm in diameter. Fine scabs appear and recovery with regrowth of hair commences in 25-30 days. Heavier scabs and larger lesions are usually due to rubbing by harness. Lesions associated with M. gypseum are smaller, about 10 mm in diameter, and are manifested either by the development of thick crusts, or more generally a diffuse moth-eaten appearance with desquamation and alopecia. Less commonly, deeper structures are infected through the hair follicles, causing small foci of inflammation and suppuration. A small scab forms over the follicle and the hair is lost but extensive alopecia and crust formation do not occur. Some irritation and itching may be caused by this type. The distribution of lesions is different - there is no pruritus or alopecia and cutaneous reaction is minimal, but the centrifugal enlargement of each lesion may cause it to reach an enormous size. Superficial, dry, brown crusts cover the affected area but are not obviously raised except at the edges in some cases. The crusts are formed of flakes or dust composed of epithelial debris. Most lesions occur on the back and sides. Spontaneous recovery does not occur in adult pigs.

**Sheep**

In sheep the lesions occur on the head, rarely in the fleeced areas and, although they usually disappear in 4-5 weeks, the disease may persist in the flock for some months. The lesions are discrete, round, almost bald patches covered with a grayish crust. Similar lesions occur in goats, but they are distributed generally over all parts of the body. The exception to this description is a new ringworm associated with an unidentified Trichophyton which has appeared in sheep in western States of USA plus Georgia and Kentucky since 1989. Lesions occur extensively in fleeced areas and are characterized by shedding of the wool staple and exudation from the skin surface. Serious spread of the infection to human attendants occurs.

**Differential Diagnosis**

The diagnosis of ringworm depends on evidence of infectivity, the appearance of characteristic lesions and the presence of fungal mycelia and spores. Diagnostic confirmation is by demonstration of fungal elements in a scraping or biopsy. The differential diagnosis list of ringworm which may be confused with diseases with similar clinical profiles.

**Cattle**

- Mycotic dermatitis, which has tenacious scabs which cover a raw area of skin
- Inherited parakeratosis, characterized by tenacious thick crusts which respond quickly and completely to dietary supplementation with zinc
- Sarcoptic mange, in which mites can be demonstrated in scrapings; there is intense pruritus and a quick response to standard insecticides
- Psoroptic mange, identifiable by the presence of mites in scrapings, pruritus, occurrence in housed cattle, and the location of the lesions over the hindquarter
Pigs
- Pityriasis rosea, in which no mites can be demonstrated and the disease is limited to a particular age group
- Exudative epidemiditis has extensive lesions with a characteristic greasy covering
- Tyrophilosis is self-limiting, associated with a new source of grain, and characterized by pruritus
- Sarcoptic mange, identifiable by the mites in scrapings, the intense pruritus and the prompt response to treatment with insecticide

Horses
- Mycotic dermatitis which is limited in its distribution to the back of the horse, and Dermatonomus congolesis can be cultured
- Queensland itch diagnosable on its occurrence only in summer, only along the back, and the associated intense pruritus
- Other equine dermatitides.

TREATMENT
Many recorded cures are no doubt due to strategic treatment just prior to spontaneous recovery, but treatment is widely practised, and recommended because it greatly reduces contamination of the environment by infected animals. Local or systemic treatments are used, the latter when lesions are widespread.

Local application
The crusts should be removed by scraping or brushing with a soft wire brush and burned; the medicament should be brushed or rubbed in vigorously. Suitable topical applications include a weak solution of iodine, Whitfield’s ointment, 10% ammoniated mercury ointment, and solutions of quaternary ammonium compounds (1:200–1:1000), propionic and undecylenic acid ointments, solutions of 0.25% hexadecamethylene-1, 16-bis(isoquino linium chloride(Tinerret), Hexedine (bis-1,3 beta-ethylhexyl-5 methyl-5-amino-hexahydropyrimidine) boronated complex, thiabendazole 1–5% ointment, the antibiotics (natamycin and nanomycin A), povodone-iodine, thiabendazole and captan ointments, and ointments containing one of the azole compounds such as imidazole or miconazole. These topical treatments are probably of greater value in the early stages of an outbreak when the lesions are small and few in number.

Sprays, washes
When infection in a group is widespread, washes or sprays which can be applied over the entire body surface of all animals are used, although the efficacy of the preparations is less than that of ointments, and daily application for at least 5 days is required. Sprays have a big advantage if prophylactic treatment of all in-contact animals is recommended. Examples are agricultural Bordeaux mixture, 5% lime sulfur (20% w/v polysulfides diluted 1:20), captan (N-(trichloromethylthio)-cyclohex-4-ene-1, 2-dicarboxamide) 3%, N-trichloromethylthio-tetrahydrophthalimide, iodofors, 0.5% sodium hypochlorite, natamycin (100 ppm).

Systemic treatment
Systemic treatments recommended for use in farm animals include the intravenous injection of sodium iodide (1 g/14 kg body weight) as a 10% solution repeated on several occasions, and, if the high cost of the treatment can be overlooked, the oral administration of griseofulvin.

Spontaneous recovery is common in individual animals and careful appraisal of results in clinical trials is necessary. Many farmers overtreat their animals with irritant preparations administered daily for long periods. A crusty dermatitis, or even a neoplastic acanthosis may result.

CONTROL
Hygiene
Failure to control an outbreak of ringworm is usually due to the widespread contamination of the environment before treatment is attempted. Isolation and treatment of infected animals, the provision of separate grooming tools, horse blankets and feeding utensils, and disinfection of these items after use on affected animals are necessary if the disease is to be controlled. Cleaning and disinfection of stables with a commercial detergent or a strong solution (2.5–5%) of phenolic disinfectant, 5% lime sulfur, sodium hypochlorite is advisable where practical. Good results are also claimed for the disinfection of buildings with a spray containing 2.0% formaldehyde and 1.0% caustic soda.

Vaccination
Vaccination has achieved a great deal of success in preventing infection in cattle and horses in most countries of Europe and Scandinavia. Vaccines include those containing highly immunogenic, non-virulent strains, or attenuated strains of fungi, or those killed vaccines containing specific fractions of mycelia. Vaccination of all animals in the group is recommended, and isolation and treatment of infected animals and disinfection of premises and gear must be carried out at the same time.

The vaccine is almost totally without side effects except for very rare deaths due to anaphylaxis, apparently related to keeping reconstituted vaccine for too long a period. Existing cases of ringworm may be exacerbated.

Nutrition
Although ringworm occurs in well-nourished as well as poorly fed animals, there does seem to be a tendency for the latter to become infected more readily and to develop more extensive lesions. Supplementation of the diet, particularly with vitamin A to young housed animals, should be encouraged as a preventive measure.

Treatment
Parenteral iodides. Ampicillin

Control
Hygiene, slaughter, vaccination
ETIOLOGY
The cause is a fungus, Histoplasma capsulatum var. farciminosum, a dimorphic fungal soil saprophyte. The organism has also been classified by the genus name Zygomycena, Cryptococcus, Saccharomyces, or Blastomyces.

The disease is listed by the OIE, to which it is notifiable.

EPIDEMIOLOGY
The disease occurs as outbreaks in horses, donkeys and mules. Outbreaks occur in autumn and winter or when large numbers of horses are gathered together for military or other purposes. The disease was detected in 1.0 to 19% of horses in Ethiopia over a 6-month period.1,2 The mortality rate is 10–15%, but the course is prolonged. Cattle and camels are rarely affected.

Fungal spores are carried from infected animals by direct contact or on bedding, grooming utensils, horse blankets or harness, and gain entry through abrasions, usually on the lower limbs. A saprophytic stage in the soil has been suggested to account for the difficulty experienced in eradicating the disease. The organism has been isolated from the alimentary tract of biting flies and they may play a role in the transmission of the disease.

Zoonotic potential
Infection is reported in humans.3

PATHOGENESIS
After gaining entry through wounds, the fungus invades subcutaneous tissue, sets up a local granuloma or ulcer and spreads along the lymphatic vessels. The ocular form of the disease results from inoculation of the organism into the eye, likely by biting flies.

CLINICAL FINDINGS
The disease is primarily an ulcerating, suppurative, pyogranulomatous dermatitis and, in most cases, lymphangitis.4 An ocular form of the disease is characterised by an ulcerating conjunctivitis.

In the cutaneous form of the disease, an indolent ulcer develops at the portal of entry, making its appearance several weeks to 3 months after infection occurs. A spreading dermatitis and lymphangitis, evident as corded lymphatics with intermittent nodules, develops. Nodules rupture, discharging a thick creamy pus. Local lymph nodes also enlarge and can rupture. Thickening of the skin in the area and general swelling of the whole limb are common. The lesions are quite painless.

The lesions usually develop on the limbs, particularly about the hocks, but may also be present on the back, sides, neck, vulva and scrotum. Occasionally lesions appear on the nasal mucosa just inside the nostrils and do not involve the nasal septum. Ocular involvement is manifested by keratitis and conjunctivitis. Sinusitis and pneumonia occur in other forms of the disease.

The disease is chronic, persisting for 3–12 months. Spontaneous recovery occurs and immunity is solid after an attack but many animals are destroyed because of the chronic nature of the disease.

CLINICAL PATHOLOGY
Gram-positive, yeast-like cells, with a characteristic double-walled capsule, are easily found in discharges. The organisms are located both extracellularly and intracellularly in giant cells and macrophages. The agent can be cultured on special media but the fungus dies quickly in specimens unless these are collected in antibiotic solutions, refrigerated and cultured promptly. The specimen should be collected into a solution containing 500 units/mL penicillin.

The mallein test is negative but a sterile filterate of a culture of H. capsulatum var. farciminosum has been used in a cutaneous sensitivity test5 and several serological tests, including a fluorescent antibody test,6 are available. Antibodies to H. capsulatum var. farciminosum are detectable in serum before or at the time of development of lesions.4

NECROPSY FINDINGS
Lesions are usually confined to the skin, subcutaneous tissues, and lymph vessels and nodes. In some cases granulomatous lesions may be found in the lungs, liver and spleen. Histologically, the lesion is quite characteristic and consists of pyogranulomatous inflammation with fibroplasia. Langerhans giant cells are common. The presence of numerous organisms, some of which show budding, in both intra- and extracellularly in tissue sections stained with H&E, Periodic acid–Schiff reaction and Gomori methenamine–silver stain is of diagnostic value.4

DIFFERENTIAL DIAGNOSIS
See Table 22.3.

- Glands (Burkholderia mallei)
- Ulcerative lymphangitis (Corynbacterium pseudotuberculosis)
- Sporotrichosis (Sporothrix schenckii)
- Histoplasmosis (Histoplasma capsulatum)

TREATMENT AND CONTROL
Many treatments have been tried, largely without success. Parenteral iodides have been reported as effective in some cases as has amphotericin. Sodium iodide is administered as a 10% solution at a dose of 1 mL per 5 kg intravenously once weekly for 4 weeks.7 Amphotericin is administered at a dose of 0.2 mg/kg body weight every 48 hours for 3 treatments.

Outbreaks in uninfected areas are probably best controlled by slaughter of affected animals. In enzootic areas severe cases should be destroyed and less severe cases kept in strict quarantine while undergoing treatment. All infected bedding, harness and utensils should be destroyed or vigorously disinfected. Formalinized aluminum hydroxide adsorbed, and heat-attenuated vaccines8 have been widely used, apparently with success.

REFERENCES

Sporotrichosis
Sporotrichosis is a contagious disease of horses, cats, cattle and humans characterized by the development of cutaneous nodules and ulcers on the limbs that may be accompanied by lymphangitis.

ETOLOGY
Sporothrix schenckii (Sporothrix beteriannii, S. schenckii, S. equi), is a Gram-positive dimorphic fungus that forms single-walled spores. The organism survives in a mycelial phase on living or decaying plant material but changes to a yeast phase when it enters a mammalian body through a puncture wound or bite.

EPIDEMIOLOGY
The disease is reported to occur in Europe, India, the United States and likely occurs throughout the world. The host range includes humans, horses, cattle, cats, camels, mice, rats, and chimpanzees.1 Economic loss caused by sporotrichosis is not great because the disease spreads slowly, the mortality rate is low, and treatment is effective. Outbreaks of sporotrichosis in dairy cattle caused reduced milk production.2
The causative agent persists in organic matter, and contamination of cutaneous wounds can occur either by contact with discharges from infected animals, or from contaminated surroundings. The disease is readily spread from affected cats to humans. Transmission from horses to humans has not been reported.

Pathogenesis, clinical findings and clinical pathology
Local invasion through wounds results in the development of abscesses and discharging ulcers. Multiple, small, cutaneous nodules develop on the lower parts of the legs, usually about the fetlock. The nodules may follow lymphatics and extend to the proximal limb. The nodules are painless, develop a scab on the summit, discharge a small amount of pus and heal in 3–4 weeks. Succeeding crops of lesions may cause the disease to persist in the animal for months. Lymphangitis, causing cording of the lymphatics occurs.

Demonstration of Gram-positive spores in discharges is diagnostic, but difficult because of their low number in horses and cattle, as opposed to the high number of spores present in lesions in cats. The organism can be demonstrated in air dry smears of exudate stained with Wright’s stain or Romanowsky stain. The hyphal stage is rare in tissues. Injection of pus into rats or hamsters produces a local yeast-like cells. The organism can be cultured on Sabouraud’s agar.

ETIOLOGY
The causes are fungi including Pythium insidiosum (syn. Hyphomycoses destruens), Basidiobolus haptosporus, or Conidiobolus coronatus.

ETIOLOGY
Pseudallescheria boydii infection causes granulomas of the lower extremities of people in tropical regions and is referred to colloquially as Madura foot. However, there is no evidence of spread of infection from horses or other infected animals to humans, although appropriate caution should be exercised when handling infected tissues, especially by individual with compromised immune function.

PATHOGENESIS AND CLINICAL FINDINGS
The life cycle of P. insidiosum involves colonization of leaves of aquatic plants where the organism undergoes sexual reproduction and produces sporangia. Motile zoospores, released from the sporangia, are attracted to plant and animal tissue, to which they adhere. Zoospores are attracted to damaged tissue on which they encyst and develop germ tubes. The hyphae invade tissue and produce the granulomatous reaction and ulceration. Ejected kunkers (necrotic material infected with hyphae) may produce sporangia.

The large (20 cm), rapidly growing, circular, fibrotic, ulcerative granulomas caused by Pythium insidiosum usually develop on the lower limbs, ventral abdomen or thorax and contain yellow concretions in sinus tracts (leeches or kunkers). The lesions are pruritic and grow rapidly, often becoming >20 centimeters in diameter in one month. P. insidiosum lesions may involve underlying bone and osteomyelitis may be a common feature of chronic pythiosis of the lower limbs. Pithyphium sp. infection of the small intestine causes eosinophilic enteritis and granuloma formation resulting in colic and the need for surgical resection. Dissemination of infection from subcutaneous sites to liver, lung and spleen occurs and results in a progressive weight loss and eventual death.

REFERENCES
C. coronatus causes lesions similar, but smaller, to those of pythiosis. However, lesions are only on the nates, nasal passages, oral cavity, pharynx, or trachea.\textsuperscript{10} The lesions can be very slow growing and take 1–2 years to become invasive, whereas others grow rapidly. \textit{Pseudallescheria boydii} causes granulomatous lesions of the nasal cavity in horses.\textsuperscript{1} \textit{B. haptosporus} causes ulcerative, granulating lesions that have a hemorrhagic, edematous surface, in contrast to the fibrotic lesions caused by \textit{Pithyium sp.}, on the sides of the trunk, thorax, neck, and head. Lesions caused by \textit{B. haptosporus} are pruritic.

\textbf{Differential Diagnosis}

- Habronemiasis
- Granulation tissue
- Sarcoma
- Fibrosarcoma

\textbf{Treatment}

The most efficacious treatment for pythiosis and conidiobolomycosis is excision, although recurrence is common (30%) with larger lesions.\textsuperscript{14} Laser ablation of the bed of the granuloma may reduce the rate of recurrence.\textsuperscript{15} Larger lesions are usually treated medically. Fungal lesions respond to treatment of \textit{sodium iodide} (20–40 mg/kg body weight, iv, q 24 h, as a 20% solution) followed by oral administration of \textit{potassium iodide} (10–40 mg/kg po q 24 h for 7–120 days). Potassium iodide can also be administered at a dose of 10 g/425 kg once daily with the dose increasing by 2 g/day until the horse exhibits feed refusal or a dose of 20 g/day is achieved. Treatment should continue until signs of mycotic disease have resolved, which is often weeks to months. An alternative to potassium iodide is ethylene-diamine dihydroiodide (1.3 mg/kg, oral q 12 h for up to 4 months and q 24 h for up to one year). Iodism is a potential adverse effect of administration of sodium or potassium iodide although this is rarely observed.

\textbf{Amphotericin} also gives good results as a systemic treatment (intravenously 0.4 mg/kg body weight increasing to 1.5 mg/kg/day for 10–40 days) combined with local infiltration and after surgical excision in extensive lesions. Administration of amphotericin can be limited by its nephrotoxicity, which should be monitored during treatment. \textbf{Itraconazole} (3 mg/kg orally every 12 hours for 3–4 months) is effective in the treatment of \textit{C. coronatus} infections of the nasal septum.\textsuperscript{16} \textbf{Fluconazole} (14 mg/kg oral loading dose followed by 5 mg/kg q 12 h orally for 6 weeks) is effective in the treatment of nasal conidiobolomycosis in horses.\textsuperscript{17} The pharmacokinetics of fluconazole in horses have been determined, permitting rationale dosing of this drug.\textsuperscript{18} \textbf{Ketoconazole} is not effective for the treatment of \textit{C. coronatus} in horses.

\textbf{Miconazole} (5 grams of 2% solution) infused for 4 weeks into lesions in the nasal cavity, in combination with systemic administration of iodides, was effective in treatment of nasal lesions caused by \textit{Pseudallescheria boydii}.\textsuperscript{11}

\textit{Scedosporium prolificans} is resistant to commonly used antifungal drugs.

A \textbf{vaccine} composed of elements of \textit{Pithyium insidiosum} causes recovery or improvement in most cases.\textsuperscript{19} It also causes a severe reaction, sometimes a cold abscess, at the injection site. Other complications include osteitis and laminitis which necessitate euthanasia.\textsuperscript{19}

\textbf{Review Literature}

\textbf{References}

\textbf{Maduro Mycosis}

A skin disease of horses characterized by cutaneous granuloma caused by a variety of fungi including \textit{Helminthosporium spiciferum}, \textit{Brachycladium spiciferum}, \textit{Curvularia geniculata} and \textit{Monosporium apiospermum}. One or more lesions 1–2.5 cm in diameter appear anywhere on the skin but with a special frequency at the coronet. The incised lesion has a mottled appearance and drains pus containing the fungus.

\textbf{Mucormycosis}

A rare disease of humans, horses, cattle, and pigs caused by coenocytic fungi of the order Mucorales.\textsuperscript{1} \textit{Absidia corymbifera} causes severe disease and death of horses.\textsuperscript{1} The disease is usually acute and progressive and antemortem diagnosis is difficult. Clinical signs include fever, diarrhea, circling, convulsions, and acute death. Horses can have ulcerating skin lesions of the muzzle, nostrils, knees and hocks can develop in animals that survive the acute disease. Necropsy examination reveals demarcated necrotic or hemorrhagic lesions in the respiratory and gastrointestinal mucosa, lungs, spleen, and brain. Thin walled hyphae are visible in routine sections of tissue examined microscopically. There is no effective treatment or control.

Diseases associated with protozoa

Babesiosis (Texas fever, redwater fever, cattle tick fever, equine piroplasmosis)

Babesia spp. are a diverse group of tick-borne, obligate, intra-erythrocytic Apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoite stage parasites into the bloodstream during the taking of a blood meal. Most babesial sporozoites directly invade circulating erythrocytes without a tissue stage of development. A few, notably, Babesia bovis, Babesia bovis, Babesia bigemina, and Babesia divergens, first invade lymphocytes where they form motile merozoites, which then invade erythrocytes. Once erythrocyte invasion occurs, a seemingly perpetual cycle of asexual reproduction is established, despite the rapid development of a strong immune response.

Cattle

Thelieriosis
Postpartum hereditary hemoglobinuria
Babesiosis
Babesioses
Sporoelastic poisoning
Leptosporangiosis
Horses
Equine infectious anemia
Paralytic myoglobinuria
Malignant hemolytic anemia
Cardiac form of African horse sickness

Treatment: Dimetacine and midocarb.

Control: Tick control, vaccination with live vaccine, chemophylaxis with midocarb.

ETIOLOGY

The nomenclature of these intra-erythrocytic parasites is still subject to change; the current list is:

- Cattle: There are four species of bovine Babesia now recognized: Babesia bovis (includes B. argentina, B. berbera, B. colchica, B. bigemina, B. divergens (B. caucasica, B. occidentalis, B. karelica) and B. major.
- Sheep and goats: B. motasi, B. ovis
- Pigs: B. tarusnami, B. perroncitoi
- Horses: B. equi, B. caballi. B. equi might be more accurately classified as a member of the Theileriidae family.

EPIDEMIOLOGY

Geographical occurrence

The distribution of the causative protozoa is governed by the geographical and seasonal distribution of the insect vectors that transmit them (Table 26.1).

Host occurrence

Bovine babesiosis

Bovine babesiosis associated with Babesia bigemina and B. bovis is an important disease of tropical and subtropical regions in the world, including the Americas. Both species are transmitted transovarially by Boophilus ticks, but only tick larvae transmit B. bovis, whereas nymphs and adults transmit B. bigemina.

Diseases associated with protozoa

Cryptosporidiosis 1512
Giardiasis (lamblia sis) 1515

Cryptosporidiosis
Giardiasis
Neosporosis

Jaundice, fever, high case fatality rate, subclinical cases, outbreaks in tropical and subtropical countries. Occurs in cattle, sheep and goats, babesiosis is associated with B. ovis, B. motasi, and occurs in southeastern Europe, North Africa, and South America.

In Iran, B. ovis, and B. motasi, occur in sheep and goats. The prevalence of B. ovis and B. motasi in sheep and goats were 23.5%, 0.5%, and 14%, 0.5%, respectively. In Iran, the clinical signs...
of babesiosis occurred in 8% of infected sheep and 6.8% of infected goats. Splenectomized sheep can be used as a model for *B. divergens* chronic infection.11

Sheep babesiosis is of considerable economic importance in the areas infested with *Rhipicephalus bursa* which is widely distributed in the Palaearctic region between 31°–45° parallels North including the Mediterranean basin,7 the Balkans, the southern former USSR, Iraq, and Iran.

Porcine babesiosis

Associated with *B. traumanni* and *B. pereucnitai*, porcine babesiosis occurs in southeastern Europe and Africa.

Equine babesiosis (piroplasmosis)

Babesiosis in the equine species is also known as *equine piroplasmosis*. In horses, donkeys, mules, and zebras the disease is associated with *B. equi* and *B. caballi*. It occurs in much of southern Europe, Asia, and the Americas. Equine piroplasmosis due to *B. equi* and *B. caballi* are widespread in China12,13 and cause for serious concern in northeast China. Australia is free of equine piroplasmosis but did allow the temporary importation of seropositive horses into the country for the Sydney Olympic games of 2000.14 While in Australia, seropositive horses were kept at certain restricted sites.

Seroepidemiologic studies of horse breeding farms in Brazil indicate the prevalence of *Babesia caballi* at 79%. *Babesia equi* 49% in mares; 36% of foals became infected with *B. equi* within 12 months but 100% with *B. caballi* within 10 months.15 Maternal antibodies against *B. equi* and *B. caballi* in foals were 44 and 68%, respectively. Titer persisted for 1–5 months for *B. equi* and 1–4 months for *B. caballi*.

In South Africa, equine piroplasmosis is a tick borne disease of horses, mules, donkeys and zebras, associated with *Babesia caballi* and *Theileria equi*. Equine piroplasmosis is widespread in South Africa. A serological survey indicated that of all serum samples collected from all parts of the country, nearly 80% were positive for *T. equi*, and 50% were positive for *B. caballi* which was cultured from horses.16

**Wildlife babesiosis**

*Babesia odocoi* infects the cervid family including the white-tailed deer (*Odocoleus virginianus*) and the American elk and American woodland caribou (*Rangifer tarandus caribou*).17 Desert bighorn sheep (*Ovis canadensis nelsoni*) and red deer (*Cervus elaphus elaphus*) are also susceptible to infection but do not exhibit clinical signs of disease.18 *B. odocoi* is transmitted by ticks, *Ixodes scapularis* and *Ixodes dammini*.

Fetal babesiosis in domestic reindeer associated with *Babesia tarandrangi* was first described in northern Russia in 1909. *B. divergens* has caused babesiosis in reindeer in Scotland.18 Two morphologically dissimilar *Babesia* spp. have been cultured from reindeer in California.19

**Origin of infection and transmission**

Viable protozoa are present only in the bloodstream of animals in the active stages of the infection. Ticks are the natural vectors of babesiosis; the causative parasites persist and pass through part of their life cycle in the invertebrate host. Both *B. bovis* (Argentina) and *B. bigemina* pass part of their life cycle in the tick *Boophilus microplus* (recently reclassified as *Rhipicephalus sp.*, but the name *Boophilus* will be used). *Boophilus* (Margaropus) *annulatus* and *B. microplus* are the major vectors of babesiosis, but other *Boophilus*, especially *B. decoloratus* in South Africa, *Rhipicephalus*, and *Haemaphysalis* spp. also act as vectors. *Boophilus microplus* is the main vector babesiosis associated with *B. bovis* and *B. bigemina* in cattle production systems in Central and South America.20 *Ixodes ricinus* is the common carrier of *B. divergens* in the United Kingdom. *Rhipicephalus bursa* and *Haemaphysalis punctata* spp. are the vectors in sheep; *Dermacentor*, *Rhipicephalus*, and *Haemaphysalis* spp. in horses; and *Rhipicephalus* and *Boophilus* spp. in pigs.

Information on the natural or experimental tick vectors of equine babesiosis is limited. *Dermacentor nitens* is the only tick species that transmits *B. caballi* in horses in the New World. In Brazil, *Amblyomma cajennense* and *Anocenter* (*Dermacentor*) *nitens* are the most common and widespread ticks infesting horses, *A. nitens* is an important natural vector of...
B. caballi. Boophilus microplus, is the dominant tick in some areas where B. equi infection is endemic. Using conventional diagnostic methods, B. microplus collected from horses were negative for both B. equi and B. caballi. Using a nested PCR, B. equi and B. caballi DNA were detected in the blood samples of horses and in the ticks. The detection of specific B. equi and B. caballi DNA in the eggs and larvae of B. microplus suggests the possibility of both transovarial and transstadial parasite transmission.21

In Iran, five ixodid species of ticks have been collected from sheep and goats.2 The Rhipicephalus sanguineus and Hyalomma marginatum are the most common species in sheep and goats. Other tick vectors include Dermacentor degagatencus in goats and Hyalomma anatolicum, Hyalomma asiaticum in sheep.10

When adult animals become infected, they act as carriers for variable periods, up to 2 years. If they are constantly reinfected, as they are in an endemic environment, they act as carriers for life. A knowledge of the life history of the tick is most important in applied control. Those ticks that parasitize only one host are easier to eradicate and cause less spread of the disease than those parasitizing two or three hosts. Control of ticks capable of surviving on both domestic and wild animals presents a major problem.

Life cycle and development of Babesia

The development of B. bovis and B. bigemina follow similar patterns in adult Boophilus spp. Babesia spp. do not parasitize any vertebrate host cell other than erythrocytes. Each sporozoite (merozoite) penetrates the cell membrane of an erythrocyte. Once inside, it transforms into a trophozoite from which two merozoites develop by a process of merogony (binary fission) (see Fig. 26.1).

In the passage of host blood to the midgut of the tick vector, the development of two populations of ray bodies from the gamonts (gametocytes) occurs.22 The ray bodies undergo further multiplication within the erythrocytes which continues after they have emerged. Large aggregations of multinucleated ray bodies, but once division is complete, single-nucleated ray bodies that are now haploid and assumed to be gametes emerge from the aggregates and then fuse together in pairs (syngamy) to form a spherical cell (zygote). The zygote selectively infects the digestive cell of the tick gut where they multiply and then the basophilic cells where further multiplication occurs with development to kinetes that escape into the tick hemolymph. In the gut cells, schizogony occurs with the formation of polyploid kinetes (large merozoites). These motile club-shaped kinetes then escape into the hemolymph and infect a variety of cell types and tissues, including the oocytes where successive cycles of secondary schizogony occurs. Thus, transovarial transmission occurs with further development occurring in the larval stage. Kinetes enter the salivary glands and are transformed into multinucleated stages (sporogony) and then break up to form sporozoites. In all species, sporozoite development usually only begins when the infected tick attaches to the vertebrate host. In B. bigemina, some development occurs in the feeding larvae, but infective sporozoites take about 9 days to appear and therefore only occur in the nymphal and adult stages of the tick. Transmission can occur throughout the rest of the nymphal stage and by adult females and males. For B. bovis, the formation of infective sporozoites usually occurs within 2 to 3 days of larval tick attachment.

Contaminated needles and surgical instruments can transmit the infection physically. The ease with which infection can be transmitted in this way depends largely on the degree of parasitism occurring with each species. Thus, the chances of physical transmission are slight with B. bovis and high with B. equi and B. bigemina.

Immunity and susceptibility to infection

The immune response of cattle to infection with B. bovis or B. bigemina involves both innate and acquired immune mechanisms.22 The immune response directed against infections with Babesia involves both humoral and cellular mechanisms and is T-cell dependent. In addition, an age-related immunity to initial infection with B. bovis in cattle is well established, characterized by strong innate immunity in young calves. Mononuclear phagocytes are engaged as the primary effector cells on innate and primary immune responses and nitric oxide has been identified as at least one babesiacidal molecule produced by activated mononuclear phagocytes. When B. bovis infected erythrocytes grown in culture are exposed to nitric oxide, death of the parasites occurs rapidly within the erythrocyte.

Innate immune mechanisms

There is an age-related immunity to primary infection of cattle with B. bovis and B. bigemina. Young calves possess this strong innate immunity against B. bovis infection that lasts for approximately 6 months after birth and is abrogated with the removal of the spleen.23 Interleukin IL-12 and IL-10 are important immunoregulatory cytokines.24 The protective innate response in young calves to infection with virulent B. bovis involves the early appearance of IL-12 and interferon-γ (IFN-γ) transcripts in the spleen. This is followed by a brief period of inducible nitric oxide synthase expression.25 In contrast, IL-12 and IFN-(mRNA) expression in the spleens of adult cattle which died from infection was delayed and depressed and occurred within the context of IL-10 expression. Also, in contrast to calves, there was no detectable antibody response before death in adults.

Acquired immune mechanisms

Following B. bovis infection, antibodies directed against protective and non-protective parasite antigens and host antigens are produced.22 Hyperimmune serum from cattle infected with B. bovis many times, or a mixture of IgG1 and IgG2 prepared from hyperimmune serum of cattle can be used to immunize naive calves passively against B. bovis infection, and the protection is strain specific. Splenectomized calves given hyperimmune serum and challenged with B. bovis recover as effectively as intact calves.

Strong immunity occurs after natural infection with most Babesia spp. There appears to be little relationship between the degree of immunity and the level of antibodies in the serum. If the infection recurs repeatedly the immunity is permanent. If the illness is treated urgently and efficiently, and the protozoa are killed before antibodies are produced, no immunity occurs. If the infection is not repeated the protozoa survive in the host for a variable time, usually about 6 months, and then disappear. A sterile immunity persists for a further 6 months and the host is susceptible again about a year after infection occurred. These periods of latent infection and resistance to reinfection are subject to significant variation and to different responses between breeds of cattle and the species of Babesia.

Despite the potential severity of the acute infection, individuals who survive generally develop immunity against disease, but not against infection, and could remain persistently infected. In the case of B. bovis, infections can persist for years, and even for the lifetime of the animal. Babesial infections have adapted well to survival in immune hosts. At least five different phenomena are known to contribute to parasite survival: rapid antigenic variation, cytoadhesion and sequestration, binding of host proteins to the infected red blood surfaces; the monoallelic expression of different members of multigene families; and establishment of transient immunosuppression.25
Endemic stability is defined as the state where the relationship between host, agent, vector and environment is such that clinical disease occurs rarely or not at all.22 Endemic stability (herd immunity) in bovine babesiosis occurs when the rate of transmission (inoculation rate) of Babesia spp. by the tick vector is sufficient to immunize a majority of susceptible calves before the loss of calfhood resistance.26 In tropical areas with a high vector population, natural exposure usually occurs at an early age and cattle are therefore immune to subsequent challenges as adults. If at least 75% of calves are exposed to B. bovis infection by 6 to 9 months of age the disease incidence will be very low and a state of natural endemic stability would exist.

B. bovis and B. bigemina across protection. Protective cross species immunity against infection cannot be induced with B. bovis and B. bigemina.22

Duration of immunity. Cattle develop a durable long lasting immunity after a single infection with B. divergens, B. bovis, or B. bigemina. Immunity to both B. bovis and B. bigemina lasts at least 4 years. There is evidence in the literature suggesting the presence of antibodies is not necessarily an indication of immunity nor is absence of detectable antibodies necessarily an indication of a lack of immunity.22

Risk factors
Host factors
Bos indicus breeds of cattle are much more resistant to babesiosis than Bos taurus breeds. This phenomenon is thought to be a result of the evolutionary relationship between Bos indicus cattle, Boophilus spp. and Babesia.22 Zebu and Afrikaner cattle have a higher resistance to B. bovis than British and European breeds; Santa Gertrudis and cross-bred cattle occupy an intermediate position. Zebu-type cattle also enjoy a relative freedom from the disease because of their resistance to heavy infestations with ticks.

In Australia, B. bigemina is usually of lower pathogenicity than B. bovis and rarely lethal even when fully susceptible adult cattle are introduced to an endemic area.22 Inoculation studies with B. bigemina in Australia have shown that B. indicus and B. indicus cross cattle are more resistant than the B. taurus cattle.22

Age resistance. There is a variation in susceptibility to infection according to age in cattle. The severity of clinical babesiosis increases with age. Calves and foals from naive dams are highly susceptible to infection and clinical illness from birth to 2 months of age, at which time they develop an innate resistance that persists to about 6 months of age. Calves and foals from immune dams
receive antibodies via the colostrum, and this passive immunity persists for 3–4 months after birth. The greatest infection rate is in animals in the 6 to 12-month age group; infection is uncommon in animals over 5 years of age. Animals under 1 year of age are infected predominately with *B. bigemina* and those over 2 years of age by *B. bovis*. Calves up to 1 year of age, although fully susceptible to infection, are resistant to disease.2 The average age at which calves in endemic areas become infected is 11 weeks (2–34 weeks), but at this early age clinical signs and pathological changes are mild and short-lived. After 6 months of age the number of infected animals in enzootic areas increases.

In housed cattle, the level of antibodies in the patient are at their lowest when the cattle come out of the barn in the spring, and gradually increase as they are exposed to vector ticks.

In enzootic areas, the animals most commonly affected by clinical disease are susceptible cattle introduced for breeding purposes, for slaughter, or in transit. Cattle indigenous to these areas are rarely affected because the natural resistance of the very young, and passive immunity via colostrum from immune dams is gradually replaced by a state of active immunity. Severe clinical cases occurring in these cattle are usually caused by exposure to some stress, such as parturition, starvation or intercurrent disease. Such breakdowns in immunity are most likely to occur if there is a superimposed infection with a different parasite, especially *Anaplasma marginale*.

Environmental factors

There is a seasonal variation in the prevalence of clinical babesiosis, the greatest incidence occurring soon after the peak of the tick population. For example, in England babesiosis is largely a disease of spring, summer, and autumn for this reason. Of the climatic factors, air temperature is the most important because of its effect on tick activity – higher temperatures increase it; humidity and rainfall have little effect – and even with temperature the effect is limited once a threshold of 7–100°C (44–50°F) minimum temperature is exceeded. Heaviest losses occur in marginal areas where the tick population is highly variable depending on the environmental conditions. In seasons when the tick population decreases, infection may die out and immunity be lost. Then in favorable seasons when ticks multiply, the infection spreads quickly amongst what has become a susceptible population. Comparable circumstances may be created artificially by an inefficient dipping program, which reduces the tick population to a low level and is subsequently unable to keep it under control.

Pathogen factors

Many intra-erythrocytic hemoparasites survive the host immune system through rapid antigenic variation which has been demonstrated for *Babesia bovis* and *Babesia rodhaini*. The molecular basis for antigenic variation in babesial parasites and its possible connection with cytoadherence and sequestration have been examined.28 The existence of different strains and antigenic variation occur in both *B. bovis* and *B. bigemina*. Babesial infections in cattle by antigenic variation and by superinfection with antigenically different parasite populations. Each change in antigenic type provides a temporary respite from attack by the host immune system and prolongs the infection period. The number of antigenically distinct relapses which can occur in a herd with babesial infection could be more than 100.

Strain differences and antigen variation do not appear to be of major importance as a cause of disease or in vaccines, since cross-immunity tests between strains usually provide adequate clinical protection against each other. *Babesia bigemina* sporozoites expressing specific antigens which induce protective immunologic responses in cattle have been characterized.29

New sequences of Spanish isolates of *B. caballi* and *B. equi* show a relatively high degree of genetic divergence within the group of piroplasms.30 The immunoreactive polypeptides of *B. equi* merozoite antigen have been identified.31

Economic importance

Bovine babesiosis is the most economically important of these diseases, because of direct losses of production and because of restriction of movement of cattle for trade by quarantine laws. Many animals die or undergo a long period of convalescence entailing loss of meat and milk production. Incidental costs of immunization and treatment add to the economic burden. With early, effective treatment the mortality rate can be reduced to 5%.

The mortality rates in outbreaks of equine babesiosis are high, but the big losses in this species result from the interference with racing and pleasure horse meetings and competitions. This is especially the case at present with the movement of horses between countries to compete in increasingly international equine competitions. An additional form of loss is the death of foals infected in utero. In the 1960s with an outbreak of clinical equine babesiosis in the United States, several cases in Australia, and several seropositive identifications in the United Kingdom, it appeared to be an emerging disease which threatened to be of major importance to the horse industry, but this has not eventuated.

The morbidity and mortality rates and the losses associated with babesiosis in other animal species are difficult to determine because they exist as enzootic diseases in areas where they occur.

Zoonotic implications

Human cases of *B. divergens* infection have been reported in France, Britain, Ireland, Spain, Sweden, Switzerland, the former Yugoslavia, and the former USSR. Geographically, they coincide with *B. divergens*-infected cattle populations and *Ixodes ricinus*-infested areas, involving inhabitants of rural areas who are exposed to ticks by virtue of their occupation or their recreational activities. Most cases are reported between May and October, during main season of tick activity. *B. divergens* is the primary cause of human babesiosis in Europe, resulting in fatality rates of 42% among persons who have been splenectomized and 5% among those with intact spleens. *B. divergens* has caused human babesiosis in North America in a splenectomized person which suggests that *B. divergens* may be emerging in North America in areas where such infections are not endemic.32 The known vector tick, *I. ricinus* is not indigenous to North America.

There is evidence that human babesiosis in the US has been associated with *B. microti*, a parasite of white-footed mice, is transmitted by deer ticks. Deer-associated zoonoses have become a major public health concern in the United States because human contact with deer ticks has increased as a result of the proliferation of deer, abandonment of farmland that reverts to thick secondary vegetation, and increased use of coastal sites for human recreation. This explains the increasing frequency of reported human cases of Lyme disease, babesiosis, and human granulocytic ehrlichiosis.32

*Babesia* represent a potential threat to the blood supply for transfusion since asymptomatic infections in humans are not uncommon and spread of the parasite via blood transfusions has been reported from various countries. Using the microaerophilous stationary phase (MASP) culture technique, the parasites proliferate in a settled layer of blood cells. This provides the opportunity to examine the basic biology of the organism, as well as the host-microbe interactions, immune factors triggered by the parasite, factors involved in innate resistance of young animals to infection, and antimicrobial susceptibility. Their in vitro cultivation can produce quantities of parasite nucleic acid
needed for defining phylogenetic relationships of these species, developing methods for detection of the parasite in otherwise asymptomatic individuals, and producing parasite antigens and attenuated strains of *Babesia* that could be used for immunization.

**PATHOGENESIS**

*Babesia* spp. are a diverse group of tick-borne, obligate, intra-erythrocytic Apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoite stage parasites into the bloodstream during the taking of a blood meal. Most babesia sporozoites directly invade circulating erythrocytes without a tissue stage of development. Once erythrocyte invasion occurs, a perpetual cycle of asexual reproduction is established despite the rapid development of a strong immune response.25

**Acute cases**

When an animal becomes infected, multiplication of the protozoa in the peripheral vessels (*B. bigemina*, *B. ovis*), or in the visceral vessels (*B. bovis*), reaches a peak with the development of clinically detectable hemolysis, the principal pathogenic effect, after an incubation period of 7–20 days. The hemolysis results in profound anemia, jaundice, and hemoglobinuria. A fatal outcome due to anemic anoxia commonly follows. In long surviving animals there are ischemic changes in skeletal and heart muscle.

In *B. bovis* infections there is also a profound vasodilatation and hypotension, resulting from stimulation of production of vasoactive substances, and an associated increase in vascular permeability. Circulatory stasis and shock follow; disseminated intravascular coagulation (DIC) and subsequent, fatal pulmonary thrombosis are also features. Cerebral babesiosis is possible.

*B. bigemina* is an uncomplicated hemolytic agent and does not exert these vascular and coagulation effects.

Susceptibility to infection with *Babesia* spp. decreases with age, but the severity of the clinical disease increases. For example, calves up to 5–6 months of age, and infected with *B. bovis*, show little effect; cattle of 1–2 years of age have a moderately severe disease; and aged cows suffer a severe, often fatal, clinical disease. Intrauterine infection of 2-day-old calf with *Babesia bovis* has been reported.18

*B. odocoieli* infection in elk causes an acute hemolytic anemia which may be fatal.17

Animals which survive become carriers, a state in which a harmles, subclinical infection is maintained by a delicate immunological balance between protozoa and antibodies. This balance is readily disturbed by the stress of transport, deprivation of food, pregnancy, or intercurrent disease. Carrier animals are resistant to infection with *B. bovis* for up to 2 years. With constant reinfecition, such as occurs in an enzootic situation, the protection is continuous, but the virulence of the blood in transmission experiments varies due to periodic disappearance of infective forms of the parasite from the peripheral blood.

The ability of cattle to infect ticks is much longer (1 year) with *B. bovis* than *B. bigemina* (4–7 weeks). Similarly, the peak incidence is at a younger age and the reinfestation rate is faster with *B. bigemina*.

In pregnant cows there is no apparent infection of the calf in utero, but passive immunity is transferred via colostrum to the newborn calf.

**Immunology**

Calves less than 9 to 12 months of age are as susceptible as adult cattle to infection with *B. divergens* but are less likely to exhibit clinical disease. This phenomenon known as inverse age resistance is due to innate resistance in calves and is independent of the maternal immune status. Although offspring of resistant dams acquire specific antibodies (mainly IgG) viacolostrum, these immunoglobulins are not necessary for protection because calves of susceptible dams without specific antibodies are equally resistant. In vitro studies with *B. bovis* show that erythrocytes of young calves were unfavorable to parasitic development, possibly because of the inhibitory effect of fetal hemoglobin.2

Cattle that recover, either naturally or after chemotherapy, from acute infection with *B. bigemina* or *B. bovis* remain persistently infected and resistant to further disease upon reinfestation with the same strain.30 Immunization with killed parasites or parasite extracts can afford protection against homologous and heterologous strain challenge, indicated by low parasitemias and diminished reduction in packed cell volume.

Immunity does not last indefinitely, and in the absence of exposure to further infection, the animal becomes susceptible to reinfestation. Specific immune mechanisms include both cellular and humoral components. Monocytes and lymphocytes are the main agents of cell-mediated immunity. Experimentally, the exposure of cattle to avirulent and virulent strains of *B. bovis* causing a primary infection, results in considerable antimicrobial activity in peripheral blood monocytes and neutrophils.37 The elevated antimicrobial activity is coincident with the time that parasite numbers peaked in the circulation and occurs prior to parasite clearance. This suggests that peripheral blood monocyes and neutrophils are active mediators in the innate immune response to a primary infection with *B. bovis*. In cattle vaccinated against *B. divergens*, protection is correlated with elevated mononuclear cell proliferation.

In cattle infected with *B. divergens*, antibodies can be demonstrated even before infected erythrocytes appear in blood smears, indicating that they have no inhibitory effect on parasite multiplications. During secondary infections, protection seems to depend on the high specificity of some antibodies rather than the total level of anti-*B. divergens* antibodies, as resistant animals frequently have very low levels of specific antibodies.

The importance of the spleen in the specific immune response is illustrated by the fact that removal of the spleen following recovery may result in clinical relapse.

Specific antibodies to the parasites are produced and are used in serological diagnosis. The highest titers are obtained in the sera of cows that have had a series of infections and reinfecions, but the degree of immunity resulting is not related to the antibody titer. The antibodies can be passively transferred via serum or colostrum. The immunity to each strain of *B. bovis* is specific. However, when an infection with a heterologous strain of the protozoa occurs, there is an increased immune response.

Experimental transmission of *B. ovis* infection in sheep produces an acute attack of clinical illness, parasitemia, and the subsequent development of immunity, as in cattle. Experimental infection of pregnant cattle with *B. bigemina* results in an immune response similar to nonpregnant animals.38

**CLINICAL FINDINGS**

*Cattle*

*Babesia bovis*. The acute disease generally runs a course of 3 to 7 days and a fever of >40°C is usually present for several days before other signs become obvious.2 This is followed by inappetence, depression, polyptena, weakness and a reluctance to move. Hemoglobinuria is often present (known as redwater in some countries); urine is dark-red to brown in color and produces a very stable froth. Anemia and jaundice develop especially in more prolonged and severe cases. Diarrhea may occur. Muscle wasting, tremors and recumbency develop in advanced cases followed terminally by coma. Many severely affected animals die precipitately at this point, after an illness of only 24 hours. Metabolic acidosis is present in a significant percentage of cases of bovine babesiosis in Ireland.39

During the fever stage, pregnant cattle
may abort and bulls may become sterile for 6 to 8 weeks. Cerebral babesiosis is manifested by incoordination followed by posterior paralysis, or by mania, convulsions and coma. The mortality rate in these cases is high in spite of treatment.

In those that survive, the febrile stage usually lasts for about a week and the total course about 3 weeks. Animals that survive recover gradually from the severe emaciation and anemia, which are inevitable sequelae.

A subacute syndrome also occurs, especially in young animals, in which the fever is mild and hemoglobinuria is absent. The syndrome in infection with *B. divergens* is similar to the above, except that in addition, there is spasm of the anal sphincter causing the passage of feces with great force in a long, thin stream, even in the absence of diarrhea. The sign is referred to as 'pipe-stem' feces.

*Babesia bigemina*. Hemoglobinuria is present earlier and more consistently than in *B. bovis* infections and the fever is less of a feature. Acutely affected animals are usually not as severely affected as those with *B. bovis* infections. There is no cerebral involvement and recovery in non-fatal cases is usually rapid and complete. However, in some cases the disease can develop very rapidly with sudden and severe anemia, jaundice and death.

Animals which recover from *B. bigemina* remain infective for ticks for 8-10 months. The exper­

**Sheep**

Anemia, fever, icterus and hemoglobinuria are common.

**Horses**

The incubation period is 8–10 days. Acute cases in adults show a sudden onset of immobility and reluctance to move; some are in lateral recumbency and do not respond to stimuli. There is complete anorexia and fever of 40°C (104°F), although the fever often subsides after 1 day and becomes intermittent. Edema of the fetlocks occurs and may also be present on the head and ventral abdomen. Fecal balls are covered with thick mucus, and colic occurs frequently. Often there is no hemoglobinuria; bronchitis occurs occasionally. The mucosae are pale pink and tinged with jaundice. In *young* horses, the signs are more severe – jaundice, mucosal pallor and weakness are marked, and mucosal petechiae are evident. The course is 8–10 days. Afflicted horses may die within 24–48 hours of the first signs appearing.

**Transmission**

Subinoculation of blood to susceptible splenectomized calves is highly sensitive technique for direct detection of *Babesia* infection. In *transmission tests*, 50–100 mL of blood are injected into the recipient either SC or IV. In the latter case, the incubation period will be shorter. The recipients are examined daily and the blood examined for protozoa at the peak of the febrile reaction.

**Carrier cattle** infected with *B. bovis* and *B. bigemina* are difficult to detect because of the small number of parasites in peripheral blood. Microscopic examination of blood films is not reliable technique for detection of *Babesia*-carrier animals. The evaluation of persistence of *B. bovis* and *B. bigemina* infections requires subinoculation of blood into splenectomized calves, and measurement of the anti-babesial antibody level.

**Culture of Babesia.** Babesia divergens from the blood of *carrier cattle* can be isolated using an in vitro culture technique in sheep erythrocytes. The protozoa could be isolated 9 months after the acute babesiosis phase, and can be successfully subcultured, cryopreserved and resuscitated using culture medium. This will allow for more detailed examination of the organism.

**Preservation of live protozoa** can be effected by cryopreservation, by culture in a medium containing infected bovine erythrocytes, and in simple culture media in special machinery for long periods and in large quantities.

**PCR detection and identification of Babesia spp.**

A universal PCR assay for the detection and identification of nine of the most common pathogenic bovine, equine, and rodent piroplasms, including *B. divergens*. Following specific amplification of the parasite DNA by nested PCR, the parasite species is identified by PCR-restriction fragment length polymorphism. Various applications of the PCR have detected *B. bovis* and *B. bigemina* parasitemias at levels of 10⁷ to 10⁸.

The most recently introduced tests are an ELISA using a recombinant *B. bovis* antigen, PCR and a DNA probe, which can detect specific parasitemias at very low levels of infection. The DNA probe has the added advantage of being able to detect protozoa in necropsy specimens and in tick tissues. The PCRs are most useful because of their high sensitivity, which makes them ideal for the detection of carrier animals.

A PCR assay can detect *B. equi* and *B. caballi* from the blood of horses which have recovered from the acute phase of babesiosis. The may assume a subclinical, chronic course and the animals are carriers and may act as reservoirs of infection, and parasites are present in very low numbers in the blood and generally not detectable in Giemsa-stained blood-smears. In these horses the complement fixation test which is the official test for the diagnosis of babesiosis in horses may be negative and the PCR test is positive. A nested
PCR assay has been used to detect natural infection of *Boophilus microplus* and the blood of horses with *B. equi* and *B. caballi* in Brazil. The nested PCR is considered superior to both Wright–Giemsa-stained and primary PCR methods for the routine detection of *B. equi* in horses.

**Serology**

Diagnosis of past or present infection is adequately demonstrated by any one of a wide range of serological tests.

**Bovine**

Because of the difficulty in finding protozoa in smears in animals during the sub-clinical stages of the disease, especially in surveillance studies for the detection of the infection in herds or areas, much attention has been directed to serological tests. These are now well-established, but none of them enjoys a completely satisfactory reputation.

**Complement fixation test (CFT).** The CFT has been the most used serological test for bovine babesiosis. Other tests being assessed in field conditions include a passive agglutination test, an indirect fluorescent antibody test (IFAT), an indirect hemagglutination test, an ELISA, a microplate enzyme immunoassay (EIA), a latex agglutination test, a capillary agglutination, a slide agglutination, and a card agglutination test. All of the tests have good reputations, with the EIA being probably the most sensitive.

**Immunofluorescence antibody test (IFAT).** The IFAT has been a popular test used to distinguish between *Babesia* spp. and to demonstrate the presence of antibodies in a population. IFAT clearly differentiates between antibodies to *B. divergens* and other bovine babesias but not between *B. divergens* and *B. capreoli* from red deer.

**ELISA.** An ELISA system using a crude antigen preparation of *B. bovis* has been standardized for the detection of IgM antibodies with a specificity of 94% and sensitivity of 100%. Specific IgM antibodies against *B. bovis* first appeared on the 11th day post-inoculation in animals infested with *B. microplus* ticks and on the 19th day post-inoculation in which animals had been inoculated with infected blood.

A competitive ELISA (cELISA) is an accurate, reliable, easily standardized, and high-throughput method for detecting hemoparasite infections. The gene encoding *B. bovis* rhoptry-associated protein 1 (RAP-1) was used to develop the assay. The cELISA accurately differentiated animals with *B. bovis*-specific antibodies from uninfected animals and from animals with antibodies against other tick-borne hemoparasites (sensitivity 98.5%, 98.7% specificity).

**EQUINE**

An ELISA is available for the detection of *B. ovis* in sheep.

**NECROPSY FINDINGS**

In acute cases of babesiosis in all species, in which patients die after a brief illness and during an anemic crisis, the typical lesions are jaundice, thin watery blood, pale tissues, enlargement of the spleen which has a soft, pulpy consistency, and gross enlargement and dark brown discoloration of the liver. The gallbladder is distended with thick, granular bile, the kidneys are enlarged and dark, and the bladder contains red-brown urine. Echymotic hemorrhages are present under the epicardium and endocardium, and the pericardial sac contains an increased quantity of blood-stained fluid. A characteristic lesion in both cattle and horses is severe intravascular clotting.

In subacute or chronic cases of fairly long duration, the carcass is emaciated but hemoglobinuria is absent; the other changes observed in acute cases are present but less pronounced. Laboratory examination of smears taken from peripheral blood, from kidney and heart muscle and, in the case of suspected *B. bovis* infection, from the brain, is mandatory for clinching the diagnosis. The smears from blood and most tissues must be made within 8 hours of death, in the case of brain within 28 hours, and stained with Giemsa for the detection of *B. bovis*.

Direct fluorescent antibody staining of smears permits the use of slightly older tissues. Organ smears are still usable 5 days after collection provided they are kept stored at 22°C (72°F). With *B. bigemina* the morphology of the parasite changes quickly after the host’s death so that they resemble *B. bovis*. Blood serum collected after death can also be used for detection of antibodies in serological tests.

**DIFFERENTIAL DIAGNOSIS**

For diagnostic confirmation the presence of the insect vector must be verified before the diagnosis of babesiosis can be made, unless the animal has left an enzootic area within the preceding month. Clinically, a high morbidity and case fatality rate in cases showing jaundice with hemoglobinuria and fever are suggestive, but confirmation of the diagnosis by examination of blood smears or by transmission experiments is essential. A necropsy showing splenomegaly, jaundice, hemoglobinuria, swollen dark kidneys and liver, and myocardial ecchymoses, while highly suggestive, should also be confirmed by laboratory examination of tissues for the presence of the causative protozoa.

**Differential diagnosis list**

A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses:

**Cattle** (see Table 26.2):

- Theileriosis (*Theileria annulata*) – very similar clinically and differentiable only on laboratory examination
- Postparturient hemoglobinuria – does not require the presence of vectors, occurs only in recently calved cows in full milk and on low phosphorus diets, and is characterized by the absence of protozoa from blood and tissues
- Bacterial hemoglobinuria – characterized by a necrotic infarct under the diaphragmatic surface of the liver in cattle grazing lush pasture
- S-methyl-L-cysteine-sulfoxide (SMCO) poisoning – occurs only in cattle grazing crops of rape or other *Brassica* spp.
- Leptospirosis – occurs only in this form of the disease in calves kept in unsanitary conditions which are wet underfoot. Diagnosis of this disease depends on isolation of the leptospires.

**Horses** (see Table 26.3):

- Equine infectious anemia – has a much longer, recurrent course, occurs in sporadic cases only and is not associated with protozoa in body fluids and tissues
- Paralytic myoglobinuria – red urine is due to myoglobinuria, always associated with recent vigorous exercise and elevation of serum creatine phosphokinase levels
- Foals with alloimmune hemolytic anemia – detectable only on laboratory examination for evidence of incompatibility between the serum of the dam and the foal’s erythrocytes
- Cardiac form of African Horse Sickness – edematous lesions occur similar to those in babesiosis, but in which there is no hemoglobinuria or jaundice.
Table 26.2: Differential diagnosis of diseases of cattle in which red urine is a principal finding

TREATMENT

Primary treatment is aimed at destruction of the protozoa in the patient. Effective drugs are available for this purpose in cattle, but the initial phase of the disease is acute; if treatment is delayed for too long the animal may succumb to the anemia in spite of sterilization of the blood. When the illness is a consequence of vaccination with live vaccine, care must be taken to avoid complete sterilization of the blood before sufficient antibody is produced to provide a durable immunity. Treatment has no suppressing effect on the protozoa that are residing in the ticks parasitizing the cattle at the time.

A summary of the recommended drugs follows, but diminazene acetate, imidocarb dipropionate, amicarbalide diethionate, and phenamidine are most often used. Parvaquone, buparvaquone, and alboquone are recent introductions with good reputations from clinical trials. Tetracyclines have been used extensively, but their use in acutely sick animals has been discontinued. They find some use in simultaneous administration with living babesia in a chemosterilant situation; the parasite is controlled but effective immunization is achieved.

Cattle

For many years, three babesicides, quinurornium sulfate and several generics of it, amicarbalide isoethionate, and diminazene acetate were available in most countries for the treatment of bovine babesiosis. In the 1970s a fourth,

Imidocarb dipropionate was introduced, and it rapidly became the drug of choice in those countries that licensed it, because in addition to its therapeutic utility, it also proved to be an effective prophylactic at twice the therapeutic dose. Currently, it is the only babesicide on the market in most of Europe. Quinuronium sulfate and amicarbilide have been withdrawn because of manufacturing safety issues, and diminazene, which is widely used in the tropics as both a babesicide and a trypanocide, was withdrawn in Europe for marketing reasons.

Imidocarb is most toxic when given IV, and IM and SC administration is generally recommended. Side effects include coughing, muscular tremors, salivation, colic, and local irritation at the site of injection following high doses. While it is regarded as being slower in action than quinuronium sulfate it is the only babesicide that consistently clears the host of parasites. In the past, the persistence of small numbers of parasites in the bloodstream was deemed necessary for the maintenance of resistance to reinfection. However, the concept of premunition is no longer accepted. Premunition is used to describe resistance that is established after the primary infection has become chronic and is only effective if the parasite persists in the host. It was thought that only cattle actually infected with Babesia were resistant to clinical disease. If all organisms were removed from an animal, resistance was thought to wane immediately. However, cattle cured of Babesia infection by chemotherapy are resistant as long as the red cell is immune. This strategy is highly effective if the host is assured to be exposed to babesiosis during the period of protection, either through a tick bite in areas where babesiosis is endemic or by inoculation of live parasites. Acquired immunity then takes over from the passive drug protection, and the animal passes smoothly to a resistant state without an intermediate clinical stage. However, if infection rates are sporadic or if very high doses of imidocarb are used, as a complete inhibition of parasite development will hinder the mounting of an adequate immune response. The major problem associated with this approach is concern about drug residues in milk and beef, which has led to the withdrawal of imidocarb in several European countries.

Imidocarb (Imizol)This, and the allied drug amidocarb, are effective babesicides for cattle at the dose rate of 1 mg/kg BW. At 2 mg/kg BW it completely eliminates the parasites from the host and maintains some residual activity; non-infected cattle derive a month's resistance to clinical infection but can be infected subclinically. It can

</table>
therefore be used to protect cattle when vaccination is undesirable, e.g. pregnancy, or when exposure to infection is short lived, and as a temporary protection while awaiting vaccination. The drug can be given SC, but the hydrochloride is inclined to be irritant; the propionate is less so.

Horses and donkeys
The preferred treatment of equine babesiosis is not well-established. Many drugs have been used, but a combination of imidocarb and buparvaquone appears to be the only efficient treatment capable of eliminating B. equi infection. B. caballi is more susceptible, but it is expected to develop resistance quickly. Imidocarb must be given in a strict treatment regimen (four IM injections of 10% solution at a dose of 4 mg/kg BW at intervals of 72 hours). For B. caballi, a regimen of 2 mg/kg BW on two occasions 24 hours apart is sufficient to control an acute infection, but does not completely eliminate the babesia, and the patient may become a carrier. The hydrochloride salt of imidocarb is strongly acidic and may provoke severe local reactions in horses, therefore, the propionate is being used more. A note of warning is necessary about the treatment of donkeys, which are very susceptible to imidocarb (the LD$_{50}$ is less than 2 mg/kg BW). Buparvaquone 4–6 mg/kg BW parenterally is also capable of controlling acute babesiosis due to B. equi, but also on its own, like imidocarb, it does not eliminate the infection, allowing the horses to remain carriers. Some initial research has been done on the use of triclosan on equine and bovine Babesia infections.

The therapeutic efficacy of imidocarb, artesunate, arteether, buparvaquone and arteether + buparvaquone combination was evaluated against B. equi of Indian origin in splenectomized donkeys with experimentally induced infection. Imidocarb had deleterious effects on liver function, and the arteether + buparvaquone combination was found to be safe and may be a superior drug for treating B. equi infection.

Sheep
Diminazene aceturate is effective as a treatment in sheep (3.5 mg/kg BW on two successive days, or 12 mg/kg BW as a single dose).

Supportive treatment
In all species, treatment regimens for severely affected patients should include blood transfusions and anti-shock preparations. In chronic cases and convalescent patients, hematinics should be provided.

CONTROL (BOVINE BABESIOSIS)
Prevention and biosecurity
Prevention of introduction of the disease into a non-enzootic area depends on effective quarantine to prevent the introduction of the vector tick, and laboratory testing to ensure freedom of the importee from infection with the pathogen. The international movement of animals has become a very important matter to the horse industry where teams of pleasure horses attend competitions in other countries, and where valuable stallions move to another country for a brief period to stand at stud. There is a tendency for some countries to be very restrictive in their quarantine procedures for horses, and international relations would be enhanced if more was known about the relationship between a positive serological test and infectivity for other horses.

Eradication
Eradication of bovine babesiosis from an area depends upon eradicating the vector tick – a problem in applied entomology. It was achieved in the United States but is unlikely to be attempted again because of the high cost to local wildlife, which are potential hosts to the ticks. Other problems encountered in the eradication process include:

- Difficulty of getting a complete muster of all cattle on every dipping day
- Multihost ticks, which can be infective but temporarily not resident on a beast on dipping day
- Spread of ticks or infested cattle due to environmental activity, e.g. floods, windstorms
- Illegal movement of cattle without a permit.

A major problem is encountered when the protozoan persists through succeeding generations of the vector tick. The resistance of ticks to acaricides is also a factor relating to the infestation level of cattle.

The effect of three tick (Boophilus microplus) control strategies (none, threshold, and strategic) on endemic stability and the likelihood of babesiosis (Babesia bovis) has been examined using a spreadsheet age-class computer simulation model based on weekly tick counts from Brazil and Uruguay. The Brazil bovine population was in a naturally occurring state of enzootic stability with an inoculation rate exceeding 0.005 throughout the year. Threshold dipping strategies did not increase the risk of babesiosis. Strategic dipping resulted in an extended period of enzootic instability lasting 30 weeks which required protec-

tion of the herd by vaccination. Because of the more prolonged low winter temperature conditions in Uruguay, the bovine population was in a naturally occurring state of endemic instability, characterized by a 28-week period in which the inoculation rate was below 0.005. Strategic dipping would lead to eradication of the babesial parasite from tick and bovine populations, but would not result in eradication of the tick vector. This could lead to subsequent outbreaks if Babesia carrier animals were introduced into the herd. In both populations, strategic tick control could be accompanied by concurrent babesiosis vaccination.

Limitation of prevalence
To accomplish limitation of prevalence at economically sustainable levels requires different solutions in different circumstances as set out below. It is largely dependent on tick control by the frequent application of acaricides, chemotherapy to kill the babesia in the cattle host and, to a lesser degree, by immunization of the host cattle. These measures are only partly effective, and are time-consuming and expensive. The reason for the poor performance of vaccination procedures after a great deal of research is that the mechanisms of immunity to protozoa, especially Babesia spp. is the lack of knowledge on how immunity to these parasites works.

- Susceptible cattle moving into an enzootic area need prior vaccination
- Marginal areas next to enzootic areas where tick populations vary with climatic change so that resident cattle lose their immunity after some dry years, and are then exposed to infection when wet years foster the migration of vector ticks back into the area. Recommended techniques are vaccination before outbreaks commence, if forecasting is available, plus temporary chemoprophylaxis after outbreaks have commenced

- Enzootic areas where losses are occurring due to environmental stress or, especially, concurrent infection with a second pathogen, e.g. Anaplasma marginale, or where the tick population has been decimated by overzealous dipping; chemoprophylaxis and relaxation of the topping program are recommended. An adequate tick population is one ensuring that all cattle are infected and reinfected early and sufficiently often to maintain them in a state of constant of infection and therefore of immunity.

Vaccination
Vaccination has been done with varying degrees of success with live and dead
whole parasites, crude parasite extracts, and isolated parasite antigens. Several findings support the development of vaccines against babesiosis. First, cattle which recover from a primary Babesia infection or that have been immunized with attenuated parasites are resistant to challenge infection. Second, immunization of cattle with native Babesia antigen extracts or culture-derived supernatants containing secreted Babesia antigens elicited protective immunity against both homologous and heterologous challenge.

The features of cattle farms on which the exposure of young cattle to tick fever organisms is sufficient to ensure that immunity is high and the risk of clinical disease is low (see endemic stability, under Epidemiology) can be compared with those farms on which exposure is insufficient (endemic instability) can be compared to examine the relationships between the management of ticks and tick fever. In Queensland, Australia, the majority of cattle herds do not have sufficient exposure to B. bovis, B. bigemina or A. marginale to confer endemic stability for tick fever. For B. bovis, the major cause of outbreaks of clinical disease in Queensland, fewer than half the herds had evidence of endemic stability. The decision to leave a few ticks on cattle in an effort to induce endemic stability did increase the likelihood of endemic stability to A. marginale. However, it was ineffective, because only 26% of herds had endemic stability against all three organisms. Thus the low proportion of herds with endemic stability to tick fever organisms and the high likelihood of clinical disease, vaccination is recommended to protect dairy cattle from tick fever throughout the tick-infested area of Queensland.

Vaccination with living immunogens

Vaccines incorporating live, attenuated strains of B. bovis and B. bigemina have been used routinely or experimentally in Australia and a number of other countries. The literature on designing blood-stage vaccines against Babesia bovis and Babesia bigemina has been reviewed. The data available on the efficacy, degree and duration of immunity provided by live vaccines against B. bovis and B. bigemina infections in Australia have been reviewed. Most of the available live vaccines are produced in government-supported production facilities, in Australia, Argentina, South Africa, Israel, and Uruguay. These vaccines include bovine erythrocytes infected with selected strains. The risk of contamination of blood-derived vaccine is real and makes post-production quality control essential, and unfortunately beyond the means of many countries in endemic regions. Techniques developed in Australia over many decades have formed the basis for production of live Babesia vaccines in most countries where they are used.

Origin and purification of strains.

Since 1990, three strains of B. bovis, and one of B. bigemina (G strain) have been used to produce vaccines in Australia. After testing for virulence, immunogenicity and purity, suitable strains are preserved as master stabilates in liquid nitrogen.

Attenuation of parasites

Babesia bovis. The most reliable method of reducing the virulence of B. bovis is the rapid passage of strains through susceptible splenectomized calves. Attenuation usually occurs after 8 to 20 calf passages. Babesia bigemina. Rapid passage in splenectomized calves is not reliable but the virulence of B. bigemina decreases during prolonged residence in latently infected animals. A single B. bigemina isolate (G strain) has been used in the Australian and South African vaccines since 1972 and the early 1980s, respectively.

Vaccine specifications

Live vaccines have proven very effective and reasonably safe, particularly when vaccination is restricted to cattle less than 1 year of age, when they still have natural resistance to the disease. Parasites for vaccines are derived from splenectomized donor calves infected with attenuated strains or parasites grown in vitro. The vaccines are provided either chilled or cryopreserved. Despite the disadvantages, live vaccines provided greater than 95% protection for the life of the animals.

Frozen vaccine.

Frozen vaccine is superior to chilled vaccine because of long shelf-life which allows post-production testing of potency and safety before dispatch. Glycerol is used as cryoprotectant in Australia in preference to dimethyl sulphoxide because it allows post-thaw storage life of the vaccine for at least 8 hours. Frozen vaccine is the only product available in South Africa and Israel, and demand for it is growing in Australia. Frozen vaccines are transported in suitably insulated containers with liquid N₂ or solid CO₂ as refrigerant which limits the ability to supply vaccines to all destinations. To ensure infectivity, the prepared vaccine must be used within 8 hours of thawing, and once thawed should not be refrozen. If glycerol is used, a thawed vaccine can remain viable for only 8 hours at temperatures ranging from 4 to 30°C. A frozen bivalent B. bovis and B. bigemina vaccine and frozen monovalent B. bovis and B. bigemina vaccines using dimethyl sulphoxide as the cryoprotectant are produced in South Africa and Israel, respectively. If dimethyl sulphoxide is used, a vaccine should be used within 30 minutes of thawing.

Chilled vaccine.

Most of the babesiosis vaccines produced to date have been provided in a chilled form. In Australia, 35 million doses were supplied between 1996 and 2003. It is popular because of ease of production, ease of transportation even with limited resources, ease of use, and low cost. The chilled vaccines currently used in Australia contain 1 x 10⁶ B. bovis, 2.5 x 10⁶ B. bigemina and 1 x 10⁶ Anaplasma centrale organisms per 2 mL dose. Chilled vaccine has a very short shelf-life, which is currently 4 days in Australia, which requires rapid, reliable means of communication and transportation to ensure viability. Chilled vaccines can remain viable for up to a week if stored at 4°C.

To reduce the risk of neonatal hemolytic disease in calves (alloimmune hemolytic anemia) of vaccinated dams, the vaccine should not be used repeatedly; most owners vaccinate only young animals seldom more than twice. Reduction of the dose rate from 5 to 2 mL and use of a cell free diluent has eliminated the problem in Australia.

The procedures to ensure quality assurance of the vaccines has been described.

The development of effective living vaccines against bovine babesiosis in Australia required laboratory and field research over the period from 1959 to 1996 is a remarkable success story of veterinary medicine. The most significant change occurred in 1964 with the traditionally used carriers of Babesia being replaced as vaccine donors by acutely infected splenectomized calves. This ensured the infectivity of the vaccine and was fortuitously associated with a reduction in the virulence of the Babesia bovis vaccine. The vaccine reduced serious losses from babesiosis in vaccinated cattle in Australia to very low levels and gained acceptance worldwide.

The demand for live trivalent tick fever vaccine containing B. bovis, B. bigemina and Anaplasma centrale produced by the Department of Primary Industries, Queensland, has increased from less than 10,000 doses in 1988 to 500,000 doses in 2001. The challenge to obtain B. bigemina parasitized erythrocytes on a large enough scale from infected splenectomized calves to meet the demand was achieved by reducing the dose rate of infected cells without affecting immunogenicity and still leave a safety margin of at least 50-fold for infectivity. This change quadrupled the potential yield of doses per calf and allowed the Department to meet the increased demand for B. bigemina vaccine.
Use of live vaccine

Cattle born in vector-infested regions. Any factor affecting the survival of the tick vectors will affect the risk of babesiosis occurring. An increased number of ticks will increase the threat of disease until an endemically stable situation develops. Conversely, reduced tick numbers will increase the longer-term risk of babesiosis due to the reduced natural exposure of calves. Therefore, cattle owners in endemic areas in Australia are advised to supplement natural exposure by vaccinating calves at weaning age. Vaccination is also recommended if cattle are being moved within the endemic area.

Susceptible cattle imported into vector-infested country or region. Large numbers of cattle, predominantly of Bos taurus breeds are being imported into tropical, developing countries to upgrade local livestock industries. This has resulted in significant economic losses due to tick-borne diseases, including babesiosis. Vaccination of naive cattle moving from tick-free to endemic areas within Australia is usually very effective. This practice has played a crucial role in making the livestock industries in these countries more sustainable and competitive in meeting market demand with regard to breed type.

K strain B. bovis and G strain B. bigemina from Australia have been shown experimentally to be protective in South Africa and Sri Lanka. Vaccine containing these strains has also been used with beneficial results in countries such as Zimbabwe and Swaziland in Africa, Venezuela and Ecuador in South America, Malaysia and the Philippines in Southeast Asia, and islands of the Caribbean.

Control of outbreaks. Use of a vaccine in the face of an outbreak is common practice in Australia.22 Superimposing vaccination in this way on a natural infection will not exacerbate the disease, but will preempt the development of virulent infections in the proportion of the herd not yet exposed to field challenge. To prevent further exposure, the group should also be treated with an acaricide capable of preventing tick attachment from the time of diagnosis to 3 weeks after vaccination. Injectable or pour-on formulations ofivermectin and moxidectin as well as fluazuron are highly effective acaricides but do not prevent transmission of Babesia.

Clinically affected cattle should be treated as soon as possible with a suitable babesiciad. In the case of a severe outbreak, it may be advisable to treat all the cattle with a prophylactic compound (imidocarb or diminazene) and to vaccinate them later when the drug residue will not affect vaccine parasite multiplication.

Hazards and precautions of live vaccine use

Severe reactions. The likelihood of vaccine-induced reactions has been reduced with the development of attenuated strains but there is always the risk of reactions when highly susceptible, adult cattle are vaccinated. Calves 2 to 9 months of age have a high level of natural resistance and a low risk of reactions. In Argentina, vaccination is only recommended for calves while in Australia and South Africa, adult cattle can be vaccinated, providing proper precautions are taken. Concurrent infections may increase the likelihood of reactions.23 The fever associated with reactions in pregnant cows may cause abortion and in large bulls a temporary loss of fertility. In the case of valuable cows and bulls, their body temperatures should be monitored during the reaction and those with prolonged fever should be treated with a babesicide.

Potential for spread of Babesia following vaccination. There is no reliable evidence that current live vaccines may spread the disease from vaccinated to unvaccinated cattle.22

Lack of protection. Since the introduction of a standardized method of production in Australia, live babesiosis vaccines have generally proved to be highly effective. In most cases, a single vaccination provided lasting, probably life-long immunity against field infections with antigenically different strains. However, some failures have occurred and are thought to be associated with loss immunogenicity by frequent passing of the vaccine strains in splenectomized calves. This was corrected by replacing the vaccine strain. To prevent future occurrences of failure, the number of passages of the vaccine strains of B. bovis is limited by frequently reverting to a master stabilate with a low passage number. Other failures may be associated with the immune responsiveness of the host and the immunogenicity of the vaccine strain subpopulations.

A single inoculation of an attenuated vaccine containing B. bovis and B. bigemina at 6 to 9 months of age provides good, long-lasting protection both in Australia and overseas.33 At that age, the risk of vaccine reactions is minimal. The immunity following use of live B. bovis vaccine lasts for at least 4 years, and possibly less for B. bigemina.32 It is known to persist even after elimination of Babesia infections and studies on drug cured cattle suggest that the degree of acquired immunity is related to the degree of antigenic stimulation (duration of prior infection) rather than the presence of live parasites. There is no evidence of a loss of immunity with time and revaccination is unnecessary. Revaccination is advisable when there is uncertainty over the accuracy of previous procedures, to ensure all animals seroconvert or when there has been a change in the strains used in the vaccine.

An attenuated frozen vaccine containing in vitro culture-derived strains of B. bovis and B. bigemina, provided protection to 90% of vaccinated cattle against the virulent Babesia spp. field strains.36

The persistence of Babesia bovis and B. bigemina infection in Friesian cows, following vaccination with attenuated live vaccines has been shown by subinoculation of blood into splenectomized calves.40 B. bigemina persisted in some cows vaccinated 10 and 46 months, previously, and B. bovis persisted in 50% of cows vaccinated 10 and 47 months previously. Parasites of both species persisted among the serologically negative cows, whereas blood obtained from serologically positive cows failed to transmit infection. Thus in the absence of reinfection, Friesian cattle may spontaneously eliminate B. bigemina and B. bovis infection after various periods of time.

The inherent disadvantages of vaccines derived from blood of animals include the risk of reactions or contamination with pathogenic organisms, sensitization against blood groups, tick transmissibility of vaccine strains and need for a cold chain transportation.

Vaccinated cattle should be housed or kept under close observation for a month in case excessive reactions occur. A major problem in vaccination with living protozoa is the occasional apparent failure to transmit the protozoa. This may be due to the absence of the protozoa from the bloodstream of the donor at the time that the blood is drawn, or to the presence of a prophylactic drug – for example, imidocarb dipropionate – or low levels of antibody in the animal’s tissues. Revaccination is necessary in these circumstances, preferably with blood from a donor that is undergoing a severe reaction at the time.

The attenuated organisms used in unfrozen South Africa B. bovis and B. bigemina vaccines are susceptible for longer periods to the residual effect of the anti-babesial drugs diminazene and imidocarb dipropionate than the virulent field strains. The waiting periods before administration of the frozen B. bovis and B. bigemina vaccines in animals which have been treated with diminazene at 3.5 mg/kg BW, compare favorably with unfrozen vaccines at 4 and 8 weeks. The inhibitory effect of imidocarb dipropionate at 3.0 mg/kg BW on the infectivity of both frozen B. bovis and B. bigemina vaccines is longer, and requires minimum waiting
periods before administration of these vaccines of 12 weeks and 24 weeks, respectively.57

Vaccination with subunit vaccines
Subunit vaccines offer an attractive alternative to virulent or attenuated parasites.58 The vaccines are based on recombinant antigens derived from cloned DNA of protozoan parasites.58 Several protective antigens associated with merozoites or merozoite-infected erythrocytes of B. bigemina and B. bovis have been identified as possible approaches.58 Rhoptry-associated proteins may become the first targets of generic recombinant vaccines.2

Non-living vaccines
Non-living vaccines would overcome many of the inherent difficulties in production, transport and use of live vaccines.22 However, they have not been sufficiently efficacious and more research is required.

Vector control
Vector control was first used successfully to control and eventually eradicate the cattle tick Boophilus annulatus and Babesia from the United State.59,60 In 1906, an eradication program began which involved livestock owners, state officials, and the US Department of Agriculture specialists.60 The program involved three tactics. First, some pastures were rendered tick-free by excluding all host animals until the population of cattle.2

REFERENCES
COCCIDIOSIS

Etiology Many different Eimeria spp., Isospora spp.

Epidemiology Young calves, lambs, piglets, kids and, rarely, foals. Infection rate is high, clinical disease much less common, high morbidity with low case fatality rate. Occurs most commonly in crowded conditions both in barns and on pasture, especially in calves and lambs moved from pasture to feedlot. Transmitted by fecal-oral route; oocysts shed from infected animals. Immunity develops after infection; clinical disease occurs rarely in adult cattle.

Signs Diarrhea, dysentery, tenesmus, appetite normal or inappetence, mild abdominal pain in lambs, nervous signs in calves with coccidiosis in cold climates, loss of body weight, anemia in some cases but not common. Epidemics occur in calves and lambs, especially feedlot animals. Diarrhea without blood in feces of piglets. Diarrhea with large amount of blood in foals.

Clinical pathology Diagnostic number of oocysts in feces.

Lesions Ileitis, cecitis, colitis.

Diagnostic confirmation Oocysts in feces; merozoites in intestinal tissues.

Differential diagnosis Calves: Rotavirus and coronavirus diarrhea; Clastidiun perfinges type C enterotoxemia; colibacillosis due to attaching and effacing Escherichia coli. Lambs: Salmonellosis, helmintiasis; Clostridium perfinges type C enterotoxemia. Piglets: Transmissible gastroenteritis; colibacillosis; Streptococci rnasomi; Clostridium perfinges type C enterotoxemia. Foals: Salmonellosis; Foal-feet diarrhea; Rotavirus diarrhea; Clostridium perfinges type B enterotoxemia.

Treatment Supportive therapy. Coccidiostats.

Control Control population density to minimize number of oocysts ingested while immunity develops. Use of coccidiostats in feed and water supplies.

ETIOLOGY

The pathogenic coccidial species are as follows: E. auburnensis and E. wyomingensis may also cause disease in calves.

Sheep: E. arloingi A (ovina), E. weybridgenis (E. arloingi B), E. crandallis, E. ahata and E. oxinovialis (previously known as E. ninakohlyakimovae) and E. giruthi.

Goats: E. arloingi, E. faurei and E. giruthi, E. caprovincia, E. ninakohlyakimovae and E. christenseni.

Pigs: Isospora suis, E. debliecki, E. scabra and E. perminuta.

Horses and donkeys: E. leuckarti.

The eimerid coccidia are one of the most controversial groups of protozoa, and their taxonomy and classification have been debated for more than 75 years. A Controversial Roundtable was held in 2001 to initiate discussion on how a new and more comprehensive classification of eimerid coccidia can be devised.

EPIDEMIOLOGY

Occurrence and prevalence of infection

Coccidiosis occurs universally, most commonly in animals housed or confined in small areas contaminated with oocysts. The coccidia are host-specific and there is no cross-immunity between species of coccidia. Clinical disease is most common in cattle and sheep. Coccidiosis causing diarrhea in newborn piglets is a major problem in some swine herds. Coccidiosis is less common in horses, but sporadic clinical cases and deaths do occur, especially in weaning age foals.

Coccidiosis occurs most commonly in young animals, with a seasonal incidence that may be associated with the time of year young calves and lambs are brought together for weaning or moved into feedlots or fed in small areas for the winter months. The prevalence of infection and the incidence of clinical disease are also age related. In housed dairy cattle, the prevalence of infection is 46% in calves, 43% in yearlings, and 16% in adult cows.

Calves

In North America, the disease occurs most commonly in beef calves after weaning in the fall of the year and when confined and fed in small overcrowded areas during the winter months. Infection occurs commonly when weaned calves are fed on the ground resulting in continuous fecal contamination of the feed. The prevalence of infection in calves in the northwestern and midwestern part of the United States is highest in summer, fall and spring compared to midwinter (January) and early summer (June). In Canada, winter coccidiosis occurs in beef calves 6–10 months of age most commonly following a prolonged cold period or a sudden change from a moderate winter to severely cold temperature. Cold weather may act as a stressor to precipitate clinical disease in animals previously infected. Acute coccidiosis and a marked increase in the numbers of oocysts discharged will occur following the treatment of infected calves with a corticosteroid on the 20th day after infection when clinical signs are apparent, or from the 12th–15th day after infection.

Occasional outbreaks occur in nursing beef calves on pasture when they mingle near water supplies. Post-weaning coccidiosis occurs in beef calves grazing pasture in the subcoastal dry tropics of northern Queensland, Australia. It may be more severe in dry years suggesting that the oocyst challenge is less important than the immunosuppressive effect of weaning and dietary stress in precipitating clinical disease. Calves are usually weaned and yoked for 3 weeks and then turned out to graze. Severe Eimeria zuernii coccidiosis causing diarrhea, dysentery, weight loss, and death occurs with up to 10% of calves being clinically affected. The disease is most severe in hot, dry and sunny conditions when, despite heavy fecal contamination, the yard conditions remain dry and dusty, and oocysts are difficult to find.

In South Africa, the prevalence is highest in calves and the most prevalent species are Eimeria zuernii, Eimeria elliptoidalis, and Eimeria bovis. The oocyst levels in the feces of adult cows were low.

In Sweden, coccidiosis due to E. alabamensis along with other species is a common cause of diarrhea and unthriftiness in calves 2–4 months of age within the first few weeks after being placed on permanent pasture in the spring. The onset of the diarrhea coincides with the prepatent period of 6–8 days of E. alabamensis. Overwintered sporulated oocysts of several different species are the source of infection. The incidence of diarrhea is much higher in first-season grazing calves placed on pastures that had been used for cattle in the previous 5 years compared to those calves placed on different pastures not previously used by cattle. The likely primary source of infection is the calves or previous occupants of pens, with the mature cows being unimportant. Clinical coccidiosis can be reproduced by inoculation of calves with a pathogenic dose of E. alabamensis, and is most severe in calves receiving the highest number of oocysts.
Coccidiosis

Adult cattle
Coccidiosis is uncommon in adult cattle, but occasional cases and even epidemics do occur, especially in dairy cows that have calved 6-8 weeks earlier. Surveys of farms in Maryland found that 2.3% of dairy cows, 21.7% of dairy heifers, and 32.9% of beef cattle were all infected with E. bovis and all were subclinical.14 These older animals serve as a source of infection for younger calves in the herd.

Lambs
Coccidiosis in lambs is a common disease in housed flocks.15 In Germany, the cumulative incidences of E. ovipolaris and E. weybridgeensis/crandalis increased rapidly resulting in almost 100% incidence in 8-week-old lambs.

Acute coccidiosis in intensively grazed lambs in Britain occurs at about 6-8 weeks of age when the oocyst output is very high, in addition to clinical coccidiosis. There is no periparturient rise in oocyst output by the ewes. The oocyst output by grazing lambs is very large compared to the output by ewes.

Coccidiosis occurs commonly in lambs following introduction into a feedlot situation where overcrowding and other stressors are operative. Lambs moved directly from range have had almost no previous exposure to coccidia, making them highly susceptible to infection and outbreaks of clinical disease. Coccidiosis is also a major problem in rearing housed lambs in the United Kingdom.16

Goats
Coccidiosis is one of the most important diseases of goats kept in large numbers under intensive management conditions.18 The prevalence of infection may be as high as 100% in some goat farms, and higher infection rates occur in young goats in large herds.19 Kids are the major source of pasture contamination, and newly weaned kids have high oocyst counts.20 Over 13 different species of coccidia have been identified in goats from different parts of the world. Surveys in Zimbabwe reveal a population mortality of 20-40% among kids on different farms; coccidiosis is thought to be a major cause of these deaths.18 Coccidial and helminth infections may occur concurrently in goats of varying ages surveyed on farms but nematode infections do not occur in kids.21 Goat kids concurrently infected with third-stage Haemonchus contortus may gain weight more slowly.22 Goats do not shed as many oocysts and helminth eggs as do sheep,23 which may be related to their mode of feeding (browsing versus grazing).

In the Czech Republic, where the majority of goats are dairy goats, the overall prevalence of Eimeria oocysts in feces was 92%.24 Nine Eimeria spp. were identified and E. arloingi was the most common with a prevalence of 84%. The number of oocysts was lower in adults and the highest in kids and clinical coccidiosis occurred in kids 2 to 4 weeks after weaning. The disease occurs in goats in Poland where 81% of adults and 100% kids are infected, and clinical coccidiosis occurs in 50% of the kids.25 In West African Dwarf goats in Ghana, Eimeria oocysts appeared at about 20 days after birth and oocyst output in some kids reached 2.7 million oocysts per gram of feces by about 39 days after birth, followed by declines to 23,840 per gram by 55 months of age.26

Pigs
Observations suggesting the presence of neonatal porcine coccidiosis include: repeated epidemics of diarrhea in piglets 5-15 days of age; no response to therapy with antimicrobials, and failure of vaccination of the neonatal sow with E. coli bacteria in control neonatal piglet diarrhea. The peak incidence occurs between 7 and 10 days of age, and most commonly during the warm summer months when high temperatures favor the sporulation of the oocysts. Isospora suis is a common parasite on pig farms; it may be found in 90% of herds and from 25 to 50% of litters.27 The prevalence may be higher when piglets and their sows are raised on solid cement floors compared to self-cleaning floors.28 The morbidity rates are variable and the case fatality rates may be up to 20%. Rotavirus infection may occur concurrently with I. suis infection in piglets 1-3 weeks of age and may be important causes of steatorrhea, or unspecified diarrhea known as milk scour, white scour, or 3-week diarrhea. Coccidiosis associated with E. scabra has also occurred in a 40 kg finishing pig affected with severe diarrhea and weight loss, and an outbreak of severe enteritis with dysentery in grower pigs from 7 to 16 weeks of age, due to a mixture of Eimeria spp including E. porcicola has occurred. Coccidiosis has occurred in 20-week-old pigs moved from a high health status environment to a dirt lot, which suggests that high-health-status pigs are highly susceptible to coccidiosis.14 I. suis infection occurs widely in large pig-producing farming systems in Germany where the highest rate of infection occurs in litters at 3 to 4 weeks of age.29 Surveys of intestinal parasites in pigs from intensive farms in China have found I. suis infections along with other parasites.30

Surveys of pig farms in Germany, Switzerland, and Austria found 76% of the farms were positive for I. suis and oocysts were more commonly found on farms which reported diarrhea and uneven weight gain. Disinfection, floor types or treatment with toltrazuril did not affect the frequency of observations.31

Foals
Eimeria laeufkarii is a ubiquitous protozoal parasite of horses that has been reported in North America and elsewhere. In a survey of horse farms in Kentucky, 41% of foals examined were oocyst-positive, and 85% of farms had oocyst-positive foals.32 The incidence of clinical disease is much less common in foals than other species, but clinical cases and deaths do occur, particularly in recently weaned foals.

Morbidity and case fatality
In general, for most species of farm animals, the infection rate is high, and rate of clinical disease is usually low (5-10%), although epidemics affecting up to 80% may occur. The case fatality rate is usually low, with the exception of the high case fatality rate in calves with winter coccidiosis accompanied by nervous signs.33 The case fatality rate may be high in calves or lambs with no previous exposure to coccidia after suddenly being introduced to a high level of infection. In calves, body weight gains and feed consumption are commonly reduced for many weeks after acute clinical coccidiosis, and affected calves do not regain losses in body weight compared to controls.

In lambs on pasture, subclinical infections are common but there is no documented evidence that growth rate is affected even with high levels of infection. While medication with a coccidiostat may lower the infection rate, there is no difference in performance between the medicated and non-medicated groups. In lambs raised under crowded conditions indoors, the acquisition of a natural multiple species infection had no effect on growth rate, but an artificial infection with E. nintakolyakimovae resulted in severe clinical disease and a case fatality rate of 50%.

Piglets infected with I. suis have significantly reduced body weight at 7, 14, and 21 days of age. The reduction in 21-day-old weight is economically important because this weight is a component of the sow productivity index which is used as a management aid to help producers quantitatively determine the potential value of gilts as replacement animals.
Methods of transmission

The source of infection is the feces of clinically affected or carrier animals, and infection is acquired by ingestion of contaminated feed and water, or by licking the hair coat contaminated with infected feces. Oocysts passed in the feces require suitable environmental conditions to sporulate. Moist, temperate, or cool conditions favor sporulation, whereas high temperatures and dryness impede it. In general, oocysts sporulate at a range of 12–32°C (53.5–89.5°F) and require oxygen. They resist freezing down to about −7 to −8°C (19.5–17.5°F) for 2 months, but −30°C (−22°F) is usually lethal. It has been suggested that oocysts might sporulate in the winter months on the hair coat contaminated with infected feces. They resist freezing down to about −7 to −30°C (−22°F) is usually lethal. It has been suggested that oocysts might sporulate in the winter months on the hair coat contaminated with infected feces.

It has been suggested that oocysts might sporulate in the winter months on the hair coat contaminated with infected feces.

The prevalence and intensity of oocyst excretion varied with time resulting in peak values around the time of parturition (periparturient rise), particularly in the case of Eimeria bovis. Oocysts of E. zuernii, E. auburnensis were first observed in calves 3 weeks of age and the prevalence of infection increased up to 67% by 9 weeks of age. The serum antibody levels in the cows were inversely correlated with E. bovis oocyst excretion which may reflect the degree of immunity developed against the infection in the cows. Antibodies to E. bovis were present in the sera calves after the ingestion of colostrum; the levels decreased from the first week of life until the third week. Subsequently, antibody levels increased until 9 weeks of age in direct correlation with oocyst excretion.

Lambs may become infected soon after birth (before 4 weeks of age) from three possible sources of infective oocysts:

- Oocysts surviving in old fecal contamination of the lambing area from previous occupation
- Fresh oocysts constantly shed by ewes
- Fresh oocysts shed by other lambs.

The fecal oocyst burden is high at 4 weeks of age but gradually declines, so that by 5 months of age the oocyst count is similar to that of their parent ewes. Sows do not play a significant role in the transmission of I. suis infections produced from one generation of piglets to the next through contamination of the farrowing pen. Infection levels as low as 100 sporulated oocysts can result in oocysts per gram values of 100 000 and induce clinical signs of coccidiosis within 2 weeks of infection. Oocysts of I. suis cannot usually be found in the feces of sows on swine farms where neonatal coccidiosis occurs. In one survey, no oocysts of I. suis were found in sows on farms with a history of neonatal coccidiosis due to I. suis, but 82% of the sows were infected with Eimeria spp. On farms without a history of neonatal coccidiosis, the prevalence of I. suis in the sows was 0.6%. In a survey in Papua New Guinea, 83% of sows raised on concrete were infected with I. suis. In another study, of two swine herds where neonatal coccidiosis due to I. suis occurred, the sows either began to excrete oocysts, or oocyst excretion rose to a detectable level from 5 days before to 3 days after farrowing. The oocysts of I. suis can sporulate and become infected within 12–16 hours at temperature ranges of 32–35°C (89.5–95°F), which are common in modern farrowing units.

Risk factors

Animal risk factors

Acute coccidiosis occurs primarily in young animals, but may occur at any age when resistance is affected by interspecies disease or inclement weather. The prevalence of infection is usually higher in calves than yearlings or adults in the same herd, but there is also evidence of variation in Eimeria species-specific age resistance. A concurrent experimental infection of calves with the coronavirus and E. bovis may result in clinical disease and lesions that are more severe than those caused by either infection alone.

Nutritional status of the animal as a risk factor for clinical coccidiosis is well known. Early weaning of lambs at 21 days of age, followed by experimental infection, results in a failure of growth. Field observations have shown that early weaned lambs are more susceptible to coccidiosis than those weaned at a later date. This may be a reflection of lack of immunity in the younger lambs, but dietary stress in early weaned lambs may contribute to the disease. In sheep with naturally occurring coccidiosis, animals on moderate and high planes of nutrition may have more dual infections than those on a low plane of nutrition, whereas the latter group have triple and quadruple infections. Considerable numbers of oocysts can be excreted into the environment even by well-fed sheep of 14–16 months of age. Lambs kept on a low plane of nutrition were less affected by clinical coccidiosis than those kept on a high plane of nutrition. The planes of nutrition were also associated with differences in the prevalences of Eimeria spp.

In the United Kingdom, coccidiosis occurs commonly in housed lambs weaned at 6–8 weeks of age and reared on straw with a high stocking density, which provides an ideal environment for oocyst survival and sporulation. The use of coccidiostats does not affect the oocyst excretion rate, which suggests either inconsistencies in the effect of in-feed medication or the infection may be controllable in non-medicated flocks without the use of coccidiostats.

Epidemics of post-weaning coccidiosis occur in beef calves under hot and dry tropical conditions where the ingestion of oocysts is small because the conditions are unsuitable for oocyst development. Such calves have usually commenced shedding oocysts within a month of birth and can shed up to nine different species by 3–4 months. Calves developing clinical coccidiosis following weaning may be more physiologically susceptible than others.

Environmental and management risk factors

Coccidiosis occurs in all species of farm animals when environmental and management conditions result in oral exposure of large numbers of sporulated oocysts to non-immune animals. Overcrowding and feeding animals on the ground, or in
situations in which the feed and water supplies can become heavily contaminated with feces and oocysts increases the infection pressure and promotes the fecal-oral route cycle of infection. The disease occurs commonly in small beef cattle herds that raise their own replacements and finish their own feedlot cattle in small outside pens that are crowded, and the feed becomes heavily contaminated by feces. Grazing calves for the first time on permanent pastures is associated with clinical coccidiosis due to the ingestion of overwintered oocysts.¹

The occurrence of clinical coccidiosis in housed dairy cattle in The Netherlands is rare.⁶ This may be associated with management practices in which calves are individually housed during the first few weeks and subsequently housed in small groups in relatively large pens. General hygienic standards are high, and manure is frequently removed. These measures reduce the intake of high numbers of oocysts and are favorable because the intensity of coccidial infections is directly related to the number of oocysts in the environment and ingested by the animals. A low level of oocyst infection will induce immunity.

The production system can influence the development of subclinical and clinical coccidiosis. In Germany, two production systems of fattening lambs are common. In the extensive system, lambs are not weaned until slaughter with little or no concentrate feeding. In the intensive system, the lambs receive a high level of concentrates.¹⁷ In lambs naturally infected with *Eimeria* spp., the mean fattening period was significantly shorter in the intensively managed groups compared with an extensively managed group. Even if no clinical signs of coccidiosis were observed in any of the systems, based on reduced daily weight gains, the lambs were subclinically affected by coccidiosis in all systems. The highest oocyst output occurred in the extensive group which may be related to intake of straw and hay from the ground. Straw and high stocking density predispose a heavy contamination of an environment which is ideal for oocyst survival and rapid sporulation. The risk of coccidiosis increased markedly if animals have a higher intake of contaminated straw from the ground.

Pathogen risk factors

Multiple infections are most common in natural infections. A single species of coccidia may be the major pathogen, but others contribute to the disease. In some cases, clinical coccidiosis in cattle occurs only when *E. bovis* and *E. zuernii* occur together. At least 13 species of coccidia oocysts have been found in the feces of cattle in the United States, with *E. bovis* being the most prevalent. In sheep and goats, the prevalence of multiple species can be as high as 95% and 85%, respectively. In a single sheep flock, there may be as many as 10 species of *Eimeria*.³⁸ *E. ovoidalis*, *E. ovina*, *E. ahshata*, and *E. parva* are highly pathogenic, whereas *E. faurei*, *E. intricata*, *E. crandallis*, and *E. weybridgensis* are only moderately pathogenic. Similar results have been obtained in surveys done in feeder cattle brought from different geographical locations in the United States to a feedlot. While *E. bovis* and *E. zuernii* are the species most commonly associated with bovine coccidiosis, as many as 11 different species may be present in the cows and calves of one herd. *I. suis* is a major cause of neonatal or weanling diarrhea in pigs, while *E. debliecki* is not considered a pathogen. This provides evidence that coccidia have a widespread distribution wherever animals are kept.

Immune mechanisms

Immunity against intestinal coccidia consists of both cellular and humoral components. Cellular immunity is more important in resistance against reinfection than humoral immunity. Field observations suggest that coccidiosis in cattle is immunosuppressive, which may increase their susceptibility to other common infections. In experimental coccidiosis, neutrophil function may be inhibited and the feeding of decoquinate may prevent this inhibition.

The administration of dexamethasone to calves suppresses the immunological response of the animal and allows the life cycle of the coccidium to proceed unimpeded.⁸ Estradiol and progesterone can enhance cell-mediated immunity and provide some protection against the often severe wasting and debilitation in calves associated with *E. bovis* infection.³⁹

In Norway, coccidiosis is an important disease in young lambs on pasture. Most lambs spend the first few weeks of their life outdoors and have little exposure to infective oocysts, and little or no immunity is acquired. When the lambs are turned out to pastures grazed by sheep in the previous grazing season, they rapidly become infected with overwintered oocysts, mainly as a result of their habit of eating soil. Coccidiosis develops in these non-immune lambs 2–3 weeks later. The immunity induced by the first infection seems to protect most lambs from reinfections later in the grazing season. In lambs treated with sulfadimidine at 200 mg/kg BW on days 12, 13, and 14 after turnout, there is a marked reduction in the severity of the coccidial infections.

Specific immunity to each coccidial species develops after infection, so that young animals exposed for the first time are often more susceptible to a severe infection and clinical disease than other animals. In lambs, natural infection acquired at pasture and artificial infections acquired by experimental inoculation result in immunity to challenge. A single infection of as few as 50 oocysts will provoke a solid immunity to reinfection with the same species, and oocyst production ceases after about 10 days. Under field conditions, lambs are probably continually ingesting oocysts from pastures that become increasingly contaminated as the season progresses. Thus, immunity to a range of species of coccidia is boosted by frequent reinfection.⁰

Very young lambs are relatively resistant to infection with a mixture of pathogenic species of coccidia, but susceptibility increases progressively up to at least 4 weeks of age.² Lambs inoculated at 4–6 weeks of age develop severe diarrhea, whereas the same inoculum given at 1 day of age causes no clinical disease. Early subclinical infection improves the resistance of lambs to later challenge. When lambs receive a relatively heavy inoculation of oocysts during their first week of life they are relatively resistant to the pathogenic effects of some coccidia, are able to respond immunologically, and are protected from subsequent challenges.² This suggests that a challenge with coccidia, before the lamb becomes susceptible to their pathogenic effects, may help to reduce the incidence and severity of clinical coccidiosis later. Resistance to *E. zuernii* infection in calves occurs after chemotherapy, or experimental infection, with monensin or amprolium. Both drugs suppress the development of the experimental disease, during which time immunity develops. An effective immunity develops in piglets following natural or experimental infection with *I. suis*, which is the most immunogenic species of swine coccidium. Susceptible piglets are exposed to this species of infection in older swine. Piglets develop a more severe clinical disease when infected with *I. suis* at 1–3 days of age than when infected at 2 weeks of age.

Economic importance

Coccidiosis is sufficiently important economically in calves to warrant control measures. One estimate suggests that the economic losses from coccidiosis in calves amount to US$100 per animal less than 1 year of age annually.

**PATHOGENESIS**

The coccidia of domestic animals pass through all stages of their life cycle in the alimentary mucosa and do not invade
other organs, although schizonts have been found in the mesenteric lymph nodes of sheep and goats. The different species of coccidia localize in different parts of the intestine. *E. zuernii* and *E. bovis* occur primarily in the cecum, colon, and the distal ileum, whereas *E. ellipsoidalis* and *E. arloingi* affect the small intestine. *E. gilruthi* localizes in the abomasum and occasionally the duodenum.4

**Life cycle**

The coccidial life cycle is self-limiting. The unsporulated oocysts are passed in the feces and develop into the infective stage in the environment. The original single cell divides, forming four sporoblasts, each of which develops into one sporocyst, and within each sporocyst two sporozoites develop. When ingested, the wall of the oocyst breaks down and the sporocysts are released. The sporocysts then enter epithelial cells. Once within the cells the sporozoites undergo asexual multiple fission (schizogony) and become first-generation schizonts, which form numerous merozoites. After the schizont matures, the merozoites are released by rupture of the epithelial cell. New epithelial cells are again invaded and second-generation schizonts occur in the large intestine. This is followed by the release of another generation of merozoites, which invade epithelial cells and produce the sexual stages, the macrogamocyte and the microgamocyte. The second-generation schizogony and fertilization of the macrogamocyte by the microgamocyte (gametogony) are the stages of the life cycle that cause functional and structural lesions of the large intestine. As the second-generation schizonts or gamonts mature, the cells containing them slough from the basement membrane and cause hemorrhage and destruction of the cecum and colon. The oocysts are the result of fertilization of the gametocytes and are discharged at the time of rupture of the cells, which usually coincides with the onset of clinical signs of dysentery. The prepatent period varies with the species of coccidia; with *E. bovis* it is 5–20 days, and with *E. zuernii* 15–17 days. Oocyst production in calves infected with *E. zuernii* reaches peak numbers on the 19th and 20th day after experimental infection. The prepatent period of *E. alabamensis* varies from 6 to 8 days. *E. zuernii* and *E. bovis* are most pathogenic to cattle and their life cycles are similar. In calves infected with *E. zuernii*, first-generation schizogony occurs in the lower ileum, and second generation schizogony and gametogony occurs in the cecum and proximal colon. The gametocytes are the pathogenic stages and cause rupture of the cells they invade, with consequent exfoliation of the epithelial lining of the intestine. It is notable that the oocyst count is often low when the disease is at its peak, as the oocysts have not yet formed. Exfoliation of the mucosa causes diarrhea, and in severe cases, hemorrhage into the intestinal lumen, and the resulting hemorrhagic anemia may be fatal. If the animal survives this stage, the life cycle of the coccidia terminates without further damage and the intestinal mucosa will regenerate and return to normal. The patent period for *E. bovis* and *E. zuernii* varies from 5 to 12 days depending on the infecting dose of oocysts.

Treatment of calves with a corticosteroid can convert subclinical infection in calves into a peracute clinical form of the disease, which suggests that environmental, nutritional, and management factors may also act as stressors in producing clinical disease. The pathophysiological changes associated with experimental infection of calves with *E. zuernii* include a decrease in packed cell volume and reduction in plasma sodium and chloride levels. However, these are not remarkable; in naturally occurring cases the changes are not significant.

In lambs, most natural infections are composed of several different species of coccidia and there is a wide range of values in the production of oocysts from individual lambs, either in the feces from the same lamb over a period of time or in the feces from a number of lambs on any one occasion. Under practical conditions, constant reinfection occurs and waves of pathogenic stages succeed each other. The occurrence of villous atrophy in the intestinal mucosa of lambs affected by coccidiosis is probably related to the recurrence of diarrhea and loss of body weight.

However, in lambs at least, there is some doubt about the effects of coccidial infection on growth rate, feed consumption, and clinical signs in the experimental disease. There may be no obvious relationship between infective dose, the fecal oocyst production, and clinical disease. This suggests that, in lambs, the mere presence of large numbers of fecal oocysts does not constitute a diagnosis of coccidiosis and that other pathogenic factors may be involved in conversion to clinical disease. It is also possible that the large number of oocysts may represent non-pathogenic coccidia.

Severely affected calves surviving the acute phase of the disease do not regain losses in body weight unless they are fed for an additional 3–4 weeks, suggesting that bovine coccidia can have a marked effect on performance. A subclinical coccidial infection superimposed on an established, low-grade, subclinical nema-

tode infection in the small intestine may have a marked effect on the mineralization of the skeletal matrix in young adult ruminants, predisposing these animals to osteodystrophy.

The fact that multiple infections are so common may explain the variations in oocyst discharge from infected animals, but more importantly in groups of animals. New cases may develop every few days for a few weeks because of the variations in the length of the prepatent period between species of coccidia.

The **pathogenesis of the nervous signs of coccidiosis in calves is unknown.** Detailed examination of a series of cases excluded possible explanations such as:

- Alterations in serum electrolytes
- Vitamin A and thiamin deficiencies
- Lead poisoning
- Uremia, *Haemophilus somnus* meningoencephalitis
- Severity of clinical disease
- Gross alteration in intestinal bacterial flora and hepatopathy.

A labile neurotoxin in the serum of calves with 'nervous coccidiosis' has been identified using laboratory mice as test subjects, but its significance is unknown.7

The **pathogenesis of bovine winter coccidiosis**, which occurs during or following very cold weather in Canada and the northern United States, is not understood. In January, February, and March, the outside temperatures may reach −40°C (−40°F) with daily mean temperatures of −10 to −15°C (14–5°F) for several days consecutively. Such temperatures should be too cold for sporulation of oocysts in feces on the ground. There is speculation that sporulation could occur on the moist hair coats of cattle, or the endogenous stages of *E. zuernii* may be in a latent phase and reactivated by the stress of cold weather.

*Isospora suis* has at least three asexual, and one sexual, intra-intestinal multiplication cycles. All stages are most prominent in the distal half of the small intestine, but also occur in the proximal small intestine, cecum and spiral colon. The prepatent period extends from 8 to 16 days and the shedding of oocysts occurs in a cyclic pattern, with 2–3 peaks separated by intervals of about 5 days.35 This biphasic disease course results in diarrhea, villous atrophy and necrosis of intestinal epithelium at 4–6 and 8–10 days after infection.

The feces may also be negative for oocysts between the biphasic peaks. Under temperature ranges of 32–35°C (89.5–95°F) the oocysts of *I. suis* can sporulate and become infective within 12–16 hours. An extra-intestinal stage of the life cycle related to the second patent period is postulated. The lesions are most
pronounced in the small intestine, and consist of villous atrophy and focal ulceration from the destruction of villous epithelial cells, principally during the peak of aseptic reproduction. A fibrino-nectretic pseudomembrane may develop in severe cases. A combined experimental infection of I. suis and rotavirus in gnoto-biotic and conventional pigs results in a synergistic action based on a competition of rotavirus and the coccidia for mature, enzymatically active absorptive villous cells.2 The effects of neonatal I. suis infection on protein dynamics may persist after clinical recovery and could contribute to suboptimal weight gains.

Experimental reproduction. The effects of experimental Eimeria bovis infection on the metabolism of water, sodium, and potassium in calves has been examined.3,4 Although acute sublethal bovine coccidiosis alters electrolyte and water metabolism, the overall balance of electrolytes and water is largely maintained by physiologic adaptation. This supports field observations that most cases of clinical coccidiosis do not require supportive fluid and electrolyte therapy.

Piglets experimentally inoculated with I. suis at 3 days of age develop a strong level of resistance to reinfection. Piglets develop more severe clinical signs of coccidiosis when inoculated with I. suis at 3 days of age than at 19 days of age. This suggests that maturation of non-specific components of the immune system is more important in the resistance of neonatal piglets to I. suis infection than specific immune mechanisms,4

CLINICAL FINDINGS

The incubation period after experimental dosing varies between species of coccidia and animals infected. It ranges from 16 to 30 days in cattle infected with E. zuernii and E. bovis, from 14 to 18 days in sheep, and as short as 5 days in piglets. The clinical syndromes associated with the various coccidia are similar in all animal species.

Cattle and sheep

A mild fever may occur in the early stages, but in most clinical cases the temperature is normal or subnormal. The first sign of clinical coccidiosis is the sudden onset of diarrhea with foul-smelling, fluid feces containing mucus and blood. Blood may appear as a dark, tarry staining of the stool or as streaks or clots, or the evacuation may consist entirely of large clots of fresh, red blood. The perineum and tail are commonly smudged with blood-stained feces. Severe straining is characteristic, often accompanied by the passage of feces, and rectal prolapse may occur. The degree of hemorrhagic anemia is variable depending on the amount of blood lost, and in most naturally acquired cases in calves anemia is not a feature. In experimental cases of coccidiosis in lambs, due to E. ninaokaytakimonoae, although 50% of the animals died, there was no evidence of blood loss, but there was significant hemoconcentration. However, in exceptional cases, anemia is severe with pale mucosa, weakness, staggering, and dyspnea. Dehydration is common, but is not usually severe if affected animals continue to drink water.

Inappetence is common and in exceptional cases there may be anorexia. The course of the disease is usually 5–6 days, but some animals undergo a long convalescent period during which feed consumption and body weight gains are subnormal. Severely affected calves do not quickly regain the body weight losses which occurred during the clinical phase of the disease. In mild cases there is diarrhea and reduced growth rate, but not necessarily dysentery too. Subclinical cases show inferior growth rate and chronic anemia only.

Clinical coccidiosis occurs only rarely in adult cattle, and the few reports describe several animals affected over a short period of time.5 Young dairy cows may be affected commonly within 6–8 weeks after calving. Diarrhea, dysentery, tenesmus, pale mucous membrane, thickening and corrugation of the rectal wall, and rapid recovery often without treatment are common.

Coccidiosis with nervous signs

Nervous signs consisting of muscular tremors, hyperesthesia, clonic-tonic convulsions with ventroflexion of the head and neck and nystagmus, and high mortality rate (80–90%) occurs in calves with acute clinical coccidiosis.6 Outbreaks of this 'nervous form' have occurred in which 30–50% of all susceptible calves are affected. It has occurred most commonly during, or following, severely cold weather in midwinter in Canada and the northern United States. Affected calves may die within 24 hours after the onset of dysentery and the nervous signs, or they may live for several days, commonly in a laterally recumbent position with a mild degree of opisthotonos. In spite of intensive supportive therapy, the mortality is high. Nervous signs have not been reported in experimental clinical coccidiosis in calves, which suggests that the nervous signs may be unrelated to the dysentery or, indeed, even to coccidiosis.

Lambs

Coccidiosis in lambs is generally similar to that in calves, but with much less dysentery. In groups of lambs raised and fed under intensified conditions, inferior growth rate, diarrhea with or without blood, low-grade abdominal pain, gradual onset of weakness, inappetence, fleece damage, mild fever, recumbency, emaciation, and death with a course of 1–3 weeks were noted. The diarrhea may escape cursory examination of the animals, but clinical examination of affected lambs reveals a perineum smudged with feces, and soft feces in the rectum. Lambs moved directly from range pasture to a feedlot with little or no previous exposure to coccidia often develop acute disease with a high morbidity and case fatality rate.

Horses

In the horse, while there is some doubt about the pathogenicity of E. leuckarti, diarrhea of several days duration, and acute massive intestinal hemorrhage leading to rapid death have been described in foals and young horses.6

Piglets

In piglets, severe outbreaks of coccidiosis occur between 5 and 15 days of age.6 Anorexia and depression are common. There is profuse diarrhea and the feces are yellow, watery, and sometimes appear foamy. The diarrhea may persist for several days when dehydration and unthriftiness are obvious. Although affected piglets continue to suck, they become dehydrated and lose weight. Vomition may occur. Entire litters may be affected, and the case fatality rate may reach 20%. The disease may persist in a herd for several weeks or months, particularly where a continuous farrowing program is used.

CLINICAL PATHOLOGY

Oocyst count

A count of over 5006 oocysts/g of feces of ruminants is considered significant. Although counts below 500/g of feces do not usually suggest clinical disease, they may indicate a potential source of severe infection if environmental conditions for spread become favorable. Oocyst counts of over 100,000/g are common in severe outbreaks, although similar counts may also be encountered in normal sheep. The output of oocysts following an acute infection falls sharply after the peak, which may result in a critically affected animal with dysentery and low oocyst count. If oocysts are not found and the disease is suspected, merozoites can be looked for in direct smears; they do not float on the conventional concentrated sugar or salt solutions used for flotation of oocysts. The several species of coccidia can be differentiated, up to a point, by the characteristics of the oocysts.

Calves

Affected animals exposed to a large number of oocysts may develop severe dysentery a few days before oocysts appear in the
feces. However, this is not commonly observed when the feces from several affected animals are examined, and usually within 2–4 days after the onset of dysentery the oocysts will appear in the feces. The period during which oocysts are discharged in significant numbers (patent period) will vary between species of coccidia, the age of the animal, and the degree of immunity, which often makes it necessary to examine a number of animals in a group or herd rather than rely on the results from a single animal.

**Lambs**

In lambs at pasture, oocysts first appear in the feces at about 2 weeks of age. The oocyst count continues to rise in the lambs until about 8–12 weeks when the counts will be 10^5–10^9/g of feces. Thereafter, the count declines to about 500/g when the lambs are 6–12 months of age. There is also considerable variation, both between lambs and in day-to-day samples from individuals, in the numbers and species of oocysts present in the feces. Hence the need for examination of several samples over a period of several days to assess the burden.

**Piglets**

In piglets, the prepatent period varies from 4 to 7 days (most commonly 5 days) and oocysts are shed in the feces for 5–8 days after the onset of clinical signs. Piglets may develop the disease at 5 days of age, and oocysts may not be present in the feces until 3 days later. The use of a saturated sodium chloride with glucose as a flotation solution is recommended when examining piglet feces for *I. suis.*

 Necropsy examination of selected untreated clinical cases is often necessary to make the diagnosis. The disease should be suspected when piglets 5–8 days of age develop a diarrhea that responds poorly to treatment. Outbreaks of diarrhea in piglets under 5 days of age are usually associated with *Escherichia coli* or transmissible gastroenteritis. However, mixed infections are common and extensive laboratory investigations are often necessary to isolate the causative agents. The diagnosis often requires a combination of consideration of the history of diarrhea in piglets 5–15 days of age, gross and microscopic lesions, the presence of coccidial stages in mucosal smears and histological sections, and identification of oocysts in intestinal contents and feces.

In heavy infections, piglets may die before the sexual stages of the parasite develop and the diagnosis is dependent upon finding lesions, schizonts, and merozoites of *I. suis* in the middle jejunum and ileum. The developmental stages can be detected by the mucosal smear technique. A rapid field diagnostic procedure consists of staining glass slide impression smears of the mucosa of the ileum and jejunum.

**Auto-fluorescence microscopy.** This technique is superior to bright field microscopy in detecting *I. suis* oocysts after flotation and is significantly more sensitive when direct smears are examined. It does not require purification of samples and requires no agents to prepare them. The calculated detection limit of auto-fluorescence is 10 oocysts per gram (using 100 mg of feces per smear); the flotation technique provides a lower detection rate of 334 oocysts per gram of feces.

**PCR detection.** The PCR test is the most sensitive technique for the detection of *I. suis* and can be used when large numbers of samples are examined, and in experimental situations. The PCR can also be used to differentiate *Eimeria polita*, *Eimeria porcina*, and *Eimeria scabra* from *I. suis.*

**Necropsy findings**

Carcasses often have generalized tissue pallor and there is usually fecal staining of the hindquarters. In cattle, congestion, hemorrhage, and thickening of the mucosa of the cecum, colon, rectum, and ileum are the characteristic gross changes at necropsy. The thickening may be severe enough to produce ridges in the mucosa. Small, white, cyst-like bodies, formed by large schizonts, may be visible on the tips of the villi of the terminal ileum. Ulceration or sloughing of the mucosa may occur in severe cases. The lesions associated with experimental *E. bovis* infection in the small and large intestines are characterized by a fibrotic thickening and colitis. Clotted blood or bloodstained feces may be present in the lumen of the large intestine. Histologically, there is denudation of the epithelium, and merozoites may be observed in some cells. Smears of the mucosa or intestinal contents should be examined for the various developmental stages.

The necropsy findings in sheep are marked by more severe involvement of the small intestine than in cattle. Atrophy of the villi in the proximal ileum occurs in both natural and experimental infection in lambs. In experimental *E. crandallis* infection in lambs, there is loss of surface epithelial cells, atrophy of villi in the small intestine, and severe diffuse crypt hyperplasia in the small and large intestines. *E. ovina/dalis* infection in lambs causes massive invasion of the cecum, with destruction of crypt stem cells leading to denudation of the cecal mucosa. In naturally acquired coccidiosis of lambs, three types of macroscopic intestinal lesions may be recognized:

1. Flat oocyst patches, which are whitish spots 1–2 mm in diameter
2. Raised oocyst patches on enlarged villi
3. Polyps which are proliferative lesions protruding into the lumen.

All three lesions contain heavy concentrations of gamonts and oocysts. In sheep affected with *E. giru/thi*, the abomasum contains numerous nodules, 1–2 mm in diameter, similar in gross appearance to ostertagiasis. These nodules contain the large schizonts of *E. giruthi*-containing merozoites.

In piglets, the small intestines are usually flaccid, but occasionally a fibrinous enteritis may be noted. Clinical signs precede the production of oocysts, so mucosal scrapings should be examined for the presence of earlier stages of the life cycle.

**Samples for confirmation of diagnosis**

- **Parasitology** – feces (FECAL); segments of jejunum, ileum, colon (DIRECT SMEAR)
- **Histology** – formalin-fixed duodenum, jejunum, ileum, cecum, colon (LM)

**Differential Diagnosis**

**Calves** in calves, clinical coccidiosis is characterized by dysentery, tenesmus, mild systemic involvement, and dehydration. The presence of large numbers of oocysts supports the diagnosis, and necropsy findings are usually characteristic. When nervous signs occur in calves appearing to have coccidiosis, differentiation from other diseases causing brain dysfunction must be made.

**Sheep** in sheep, the diagnosis is dependent on the clinical findings of diarrhea and dysentery, the presence of large numbers of oocysts in the feces and the intestinal lesions at necropsy. Large numbers (100,000/g) of oocysts may occur in the feces of normal lambs, and thus the observation of large numbers of oocysts in the feces of lambs affected with diarrhea and/or dysentery may not, in itself, constitute a diagnosis of coccidiosis. In lambs that have had previous contact with coccidia, and that may be relatively immune, other causes of diarrhea such as salmonellosis, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia, and *Escherichia coli* enterotoxemia, *Clostridium perfringens* type C enterotoxemia. See Table 26.3 for epidemiological and clinical features of the diseases causing diarrhea in sheep and goats.

**Piglets** in piglets, diarrhea due to coccidiosis must be differentiated from enteric colibacillosis, transmissible gastroenteritis, rotavirus infection, *Strongyloides ransomi*, and *Clostridium perfringens* type C enterotoxemia. See Table 26.3 for epidemiological and clinical features of the diseases causing diarrhea in pigs.

**Foals** See Table 26.3 for the epidemiological and clinical features of the diseases causing diarrhea in foals. The common causes of diarrhea of foals include those associated with *Salmonella spp.*, *Actinobacillus equuli*, and rotaviruses.
TREATMENT
Coccidiosis is a self-limiting disease, and spontaneous recovery without specific treatment occurs commonly when the multiplication stage of the coccidia has passed. Many treatments have been recommended without taking this into account and it is unlikely that any of the chemotherapeutic agents in common use for clinical coccidiosis has any effect on the late stages of the coccidia. Most of the coccidiostats have a depressant effect on the early, first-stage schizonts and are used for control.

In an outbreak, the clinically affected animals should be isolated, and given supportive oral and parenteral fluid therapy as necessary. The population density of the affected pens should be reduced. All feed and water supplies should be kept clean and fresh, and given fluid therapy orally and parenterally. However, the case fatality is high in spite of intensive supportive therapy. Sulfadimidine therapy parenterally may be indicated to control the development of secondary bacterial enteritis or pneumonia, which may occur in calves with coccidiosis during very cold weather. Corticosteroids are contraindicated.

Calves and lambs. The chemotherapeutic agents recommended for treatment and control of coccidiosis in calves and lambs are summarized in Table 26.4. There is insufficient information available to make reliable recommendations for the specific treatment of acute clinical coccidiosis. None of these chemotherapeutic agents has been adequately tested in clinical trials. Sulfadimidine is used widely empirically for the treatment of acute clinical coccidiosis in calves. Amprolium is also used for treatment, and there may be a beneficial effect in terms of increased body weight gains and feed consumption compared to untreated controls recovering spontaneously.

Piglets. Symmetrical triazintri ones are effective against the asexual and sexual stages of experimental I. suis infection in piglets and is most effective before the onset of clinical signs.50

CONTROL
The control of coccidiosis assumes greatest importance in calves and lambs, and has been difficult to achieve with reliability.

Management of environment
Successful economical control will depend on avoiding the overcrowding of animals while they develop an immunity to the coccidal species in the environment. Only small numbers (50/day) of oocysts are required for the development of solid immunity in lambs. Lambing and calving grounds should be well drained and kept as dry as possible. Lambing pens should be kept dry, cleaned out frequently, and bedding disposed of so that oocysts do not have time to sporulate and become infective. All measures that minimize the amount of fecal contamination of hair coats and fleece should be practiced regularly. Feed and water troughs should be high enough to avoid heavy fecal contamination. Feeding cattle on the ground should be avoided if possible, particularly when overcrowding is a problem.

Lambs at pasture
In groups of lambs at pasture, the frequent rotation of pastures for parasite control will also assist in the controls of coccidial infection. However, when lambs are exposed to infection early in life as a result of infection from the ewe and a contaminated lambing ground, a solid immunity usually develops and only when the stocking density is extremely high will a problem develop.

Feedlot cattle and lambs
Control of coccidiosis in feeder calves and lambs brought into a crowded feedlot until the animals while effective immunity develops. Management procedures include establishing the optimum stocking density, which can be assessed by visual inspection. When animals are overcrowded they usually become dirty, there is excessive competition for feed supplies, and growth rate may be affected.

Piglets
The control of coccidiosis in newborn piglets infected with I. suis has been unreliable. The use of coccidiostats in the feed of the sow for several days or a few weeks prior to, and following, parturition has been recommended and used in the field, but the results are variable. Amprolium and monensin have been evaluated for the prevention of experimental coccidiosis in piglets and are ineffective. A control program designed to decrease the number of oocysts has been recommended and consists of proper cleaning, disinfection, and steam cleaning of the farrowing housing. Amprolium (25% feed grade) at the rate of 10 kg/tonne of sow's feed beginning 1 week before farrowing and continued until the piglets are 3 weeks of age has been recommended, but the results are unsatisfactory. A single oral dose of 1.0 mL of toltrazuril given to piglets 3–6 days of age reduced the occurrence of coccidiosis from 71% to 22%, and the number of days that oocysts were excreted in the feces reduced from 4.9 to 2.5.

A single treatment of toltrazuril at 20 mg/kg BW at an early stage of infection (2 days post-infection) controlled a large experimental infection with I. suis in suckling pigs.

Coccidiostats
Coccidiostats are used for the control of naturally occurring coccidiosis in calves and lambs. The ideal coccidiostat suppresses the full development of the life cycle of the coccidia, allows immunity to develop, and does not interfere with production performance. Those that have been used for treatment and control are summarized in Table 26.4.

To be effective, coccidiostats must be given beginning early in the life cycle of the coccidia. In any group of animals,
there will be several different species of coccidia at different stages of the cycle: some at the drug-susceptible stage (before 13–15 days in calves) and some beyond the drug-susceptible stage (after 16–17 days), which explains why coccidiostats appear to be effective in some epidemics and ineffective in others. In an epidemic in calves, new cases may develop for up to 12–15 days after the commencement of feeding of an effective coccidiostat to in-contact calves. However, the stage of the prepatent period is unknown at any particular point in time in the affected group, and the most that can be done is to medicate the feed and water supplies with the coccidiostat of choice, treat new cases that develop, and avoid the stressors of overcrowding and nutritional disorders.

Some comments about some of the coccidiostats are made here. Routine prophylactic medication of the feed and water supplies of feeder calves and lambs with an effective coccidiostat will usually control the disease and allow the development of effective immunity.

Antimicrobials
Sulfonamides in the feed at a level of 25–35 mg/kg BW for at least 15 days are effective for the control of coccidiosis in calves and lambs. Sulfafoximine at 55 g/tonne is also effective in goats. A combination of chlortetracycline and a sulfonamide has provided protection in calves and lambs.

Ionophores
Monensin is an effective coccidiostat and growth promoter in cattle, sheep, and goats. The recommended levels are 16–33 g/tonne for calves and 20 g/tonne for feeders. Levels of 11 g/tonne feed are not as reliable as the higher dose for calves. The recommended level for goats is 16 g/tonne of feed. A concentrated ration containing monensin at 15 g/tonne can be fed to ewes from 4 weeks before lambing until weaning, and to lambs from 4 to 20 weeks of age. Monensin can markedly reduce the oocyst output of ewes and lambs when fed before and after lambing. Withdrawal of the monensin may be followed by the development of fatal coccidiosis in some animals, presumably because the drug suppressed the development of immunity. Postweaning coccidiosis in beef calves has been controlled using monensin from intraluminal continuous release devices. The toxic level of monensin for lambs is 4 mg/kg BW.

Lasalocid is related to monensin and is also an effective coccidiostat for ruminants. For maximum benefit, lasalocid should be used daily in the feed of coccidia-susceptible lambs for as long as possible. An effective method of control is to medicate the feed of the ewes beginning about 2 weeks before lambing and continue the medication until the lambs are weaned. The lambs begin to receive lasalocid in their creep ration, and later in their rations from weaning until market. For maximum control of coccidiosis and improved feedlot performance, lasalocid should be given before and during the time that coccidia-naïve lambs are first exposed to the natural occurrence of oocysts. A level as low as 25 mg/kg of feed will control coccidiosis and improve performance when fed to lambs in early life. Similar improvements in feedlot performance do not occur in heavier lambs already passing oocysts and being fed lasalocid at 25 mg/kg feed.

Lasalocid fed at a rate of 40 mg/kg of starter to dairy calves beginning at 3 days of age, and up until 12 weeks of age, is effective in reducing fecal oocysts and increasing mean daily body weight gain, dry-matter intake, and improved feed efficiency.53 Mixing lasalocid in the milk replacer of calves beginning at 2–4 days of age is an effective method of controlling coccidiosis.60 It is also effective as a coccidiostat when fed free-choice in salt at a level of 0.75% of the total salt mixture. Lasalocid at levels from 0.75 to 3 mg/kg BW is effective in preventing experimental coccidiosis in calves. The level of 1 mg/kg BW is the most effective and rapid, and is recommended when outbreaks of coccidiosis are imminent in cattle. Lasalocid and decoquinate are effective in reducing coccidia infections in young calves under conditions of apparent low exposure and good management. However, neither lasalocid nor decoquinate, or both, added to the feed of 16-week-old dairy calves naturally infected with subclinical coccidiosis for 56 days had any significant effect on weight performance.57

Monensin, lasalocid and decoquinate at the manufacturer’s recommended levels are equally effective. A combination of monensin and lasalocid at 22 and 100 mg/kg of diet, respectively, is an effective prophylactic against naturally occurring coccidiosis in early weaned lambs under feedlot conditions. The ionophores are used in the feed continuously from weaning to market, and provide control of coccidiosis and improve feedlot performance. The continuous feeding of lasalocid, decoquinate or monensin will effectively control coccidiosis; cessation of medication may result in the appearance of oocysts in the feces and diarrhea.

Decoquinate in the feed at 0.5–1.0 mg/kg BW suppressed oocyst production in experimentally induced coccidiosis of calves.58 It is most effective in preventing coccidial infections when fed continuously in dry feed at 0.5 mg/kg BW.59 When fed to dairy calves from 9 weeks to 24 weeks of age, there was an improvement in growth rate, height at withers, and heart girth measurement.60 A level of 0.5 mg/kg BW is effective in goats.

Toltrazuril at 20 mg/kg BW as a single dose, 10 days after being turned out to pasture, will almost completely prevent coccidiosis, which occurred commonly without prophylactic medication. A dose of 15 mg/kg BW is effective to control experimental infections of calves with E. bovis.60 In addition, medication of naturally infected lambs with toltrazuril on day 10 after turnout will markedly reduce the excretion of oocysts for a prolonged period, and thus lessen the contamination of the pasture with oocysts. A single treatment of toltrazuril can significantly reduce the oocyst output in naturally infected lambs for a period of approximately 3 weeks after administration. Weekly oral treatment of sucking lambs with 20 mg/kg BW of toltrazuril reduced the oocyst output and improved weight gain over a 10-week period.61

Vaccines
The literature on the prospects for subunit vaccines against protozoa of veterinary importance has been reviewed.62 Although subunit vaccines offer many theoretical advantages, the lack of understanding of immune mechanisms to primary and secondary infection and the capacity of many protozoa to evade the host immunity remain obstacles to developing effective vaccines.

REVIEW LITERATURE

REFERENCES
Sarcocystosis (sarcoспoridiosis)

**Clinical pathology** Anemia and elevated blood concentrations of enzymes associated with tissue damage in acute disease.

**Lesions** Non-suppurative encephalitis in sheep with neurological signs. Non-suppurative encephalitis, myocarditis, and hepatitis in aborted fetuses. Cysts in carcass in chronic cases.

**Diagnostic confirmation** Identification of parasite microscopically in biopsy or postmortem material.

**Treatment and control** No effective treatment, amprolium or salinomycin may aid in control. Proper disposal of carcasses.

---

**Etiology**

Sarcocystis species are obligate two-host sporozoan parasites in the phylum Apicomplexa. There are a number of species, each with definitive omnivorous or carnivorous species as final hosts. One system of naming the species identifies the intermediate and definitive host in the name, i.e. S. bovis, and has been commonly used in the literature. However, currently the organisms are identified by their original names. Table 26.5 shows the currently accepted name of Sarcocystis species of importance in agricultural animals and their definitive hosts.

**Epidemiology**

**Occurrence** In all countries where there have been surveys, the prevalence of infection in cattle, sheep, and horses approaches 100% with a lower, but significant infection rate in swine. Clinical disease is rare.

**Source of infection** Sarcocystis spp. have an obligatory prey–predator–live-host life cycle in which the definitive host is a predator or scavenger. The carnivorous definitive host becomes infected by ingesting tissue of the intermediate host that contains mature sarcocysts. Following ingestion, bradyzoites are released from the sarcocyst in the stomach and intestine, and they transform into micro- and macrogamonts. The male microgamonts mature to release microgametes, which fertilize the macrogamet to form an oocyst. The oocyst subsequently sporulates to release sporocysts which are passed in the feces and contain infective sporozoites.

The prepatent period is variable, approximately 14 days, and there is no illness in the carnivore host in association with this cycle. However, the replicative cycle of the parasite in the intestine results in the presence of large numbers of sporocysts in the feces and the infection is **patent for a long period**. Intermediate hosts become infected by ingesting sporocysts in the food or water.

**Risk factors**

**Climate** Sporocysts are not dependent on weather conditions for maturation, and are quite resistant to environmental influences. Under experimental conditions they can survive freezing, but they are susceptible to drying. Consequently they can probably overwinter in the environment. Field studies have shown a lower herd prevalence of sarcocystosis in cattle in arid and semi-arid environments compared to cattle from temperate and tropical areas, which is probably a consequence of the relative aridity as well as the lower density of the definitive and intermediate hosts in arid areas.

Species of Sarcocysts

Individual species vary in their pathogenicity and in their ability to produce clinical disease in the intermediate host. In cattle, for example, S. cruzi is considerably more pathogenic than S. hominis.

</table>
S. tenella is the most pathogenic species for sheep, and S. capricanis for goats and naturally occurring clinical disease in sheep is not observed with S. gigantea or S. medusifonnis. There is a strong correlation between the number of sporocysts ingested and the severity of disease. The size of the sarcocyst that occurs in the tissues of the intermediate host also varies with the infecting species. Those from cats and occurring in sheep (S. gigantea, S. medusifonnis) or cattle (S. hirsuta) are of particular economic importance, as they produce macroscopically visible sarcocysts that can result in meat condemnation. S. cruzi produces microscopic sarcocysts in muscle and will escape gross detection at meat inspection.

Farm dogs
There is a positive association between herds infected with Sarcocystis and the presence of working dogs on the farm, the practice of leaving carcasses in the field and the feeding of dogs with raw meat, and virtually all of the reported clinical cases of sarcocystosis in cattle in the literature record that the dogs on the farm were fed offal or uncooked beef. Housing of dogs and cattle in the same shed or area can have increased risk for infection and clinical disease, and cattle pastured close to farm buildings where there are dogs are at greater risk. The presence of foxes on farms is also strongly associated with Sarcocystis infection in those herds that leave carcasses on the field.

Cats
The main risk for cat-associated sarcocystosis is the farm cat that is fed raw meat. Farm cats use hay barns as dens and can contaminate hay and other feedstuffs. Feral cats have the potential to distribute sporocysts widely in the grazing environment; however, the presence of feral cats on a farm may not increase the risk for Sarcocystis infection of cattle, as scavenged sheep or cattle carcasses are a relatively unimportant part of the diet of feral cats. Stacking density
Risk for infection with Sarcocystis is higher with higher stacking densities, which may reflect a more intense contamination of pastures by working dogs. Cattle on farms that graze sheep and cattle on the same pastures are less likely to be infected.

Economic importance
The major economic loss occurs with those sarcocysts that produce macroscopic cysts and meat condemnation. More severe infection depresses the growth rate, and there is a greater risk for abortion in infected herds.

PATHOGENESIS
In the intermediate host, sporozoites are released from ingested sporocysts in the small intestine where they penetrate the mucosa and enter the endothelial cells of blood vessels. The stages of schizogyne and the distribution of merozoites vary depending upon the species, but in cattle endothelial infection is followed by parasitemia, with merozoites subsequently localizing in striated muscle and nervous tissue where they develop into sarcocysts. Immature sarcocysts can be found in muscle 45–60 days following ingestion of sporocysts and are infective at about 70 days.

Schizogony in the endothelial cells of the arterioles and capillaries results in widespread hemorrhage and anemia. Fever is associated with the parasitemia, and in the experimental disease coincides with the time of maturation of the first- and second-generation schizonts. The vascular lesion appears to be an essential part of the disease's pathogenesis. It is proposed that the parasite produces growth retardation as a result of changes in plasma concentrations of somatostatin and growth hormone, and changes in cytokine interactions with the endocrine system.

The severity of the illness and the degree of infection of tissues at postmortem examination in experimentally induced cases increase with the size of the infective dose. The number of asymptomatic infections probably reflects the early ingestion of a few sporocysts that provoke a strong immunity to later challenge. When groups of animals that have not been exposed to infection previously are suddenly brought into contact with heavy contamination, especially from dogs and cats, outbreaks of clinical disease are likely to occur.

CLINICAL FINDINGS
Infection and disease can occur at all ages. Clinical disease may be more severe where there is intercurrent nutritional stress, and copper deficiency may be an exacerbating factor. Monensin is suspected of being able to potentiate recent infections to cause a severe myositis.

Cattle
Acute illness is recorded with experimental infections but is rarely seen, or recognized, in the field. Illness commences with a rise in temperature and heart rate, followed by anorexia, anemia, weight loss, a fall in milk production, nervousness, muscle twitching, hypersalivation, lameness, abortion, and, in heavy infections, death. The agent is an occasional cause of non-suppurative encephalomyelitis in cattle and manifest with ataxia and recumbency.

Chronic disease in cattle is manifest by poor weight gains, loss of hair of the neck, rump and the switch of the tail ('rat-tail'), anemia, and abortion.

Sheep
In sheep, naturally occurring sarcocystosis has been associated with S. tenella and S. arietis and presents primarily as a neurological disorder, with muscle weakness, trembling, ataxia of varying severity, followed by hind limb paresis or flaccid paralysis and lateral recumbency. All ages of sheep can be affected, although lambs under 6 months are most susceptible. Attack rates in a susceptible group can be as high as 75% with a high case fatality rate.

Infection may also be manifest with decreased growth, reduced wool growth, and anemia. Less common manifestations include signs of congestive heart failure associated with endocardial and myocardial infection. Infestation of the muscle of the esophagus in sheep is believed a cause of esophageal dysfunction and regurgitation in sheep.

Swine
Natural clinical disease is not recognized. Sarcocystosis produced experimentally in pigs is manifested by cutaneous purpura on the snout, ears, and buttocks, and dyspnea and anemia. Infection may also be manifest with depressed growth, reduced wool growth, and weakness or recumbency. There is evidence that breed of pig affects the severity of clinical disease with experimental infections and also the subsequent severity of the parasite load.

Abortion and perinatal fatality
Fetal infection, with abortion or neonatal mortality, is recorded in both cattle and sheep when pregnant animals are infected experimentally or naturally with pathogenic strains.

CLINICAL PATHOLOGY
Characteristic laboratory findings in the systemic disease include a responsive anemia, a prolonged prothrombin time, and high titers of antibody to Sarcocystis. Blood creatine phosphokinase, lactic dehydrogenase, and aspartate aminotransferase are significantly elevated. An indirect hemagglutination test (IHA) and an ELISA test are available for serological surveys. Titers of antibodies are not high at the time of an acute illness, but are at diagnostic levels 1 week to 3 months afterwards. An ELISA based on antigens from merozoites has high sensitivity and specificity for detection of infection in individual animals, and a 100% sensitivity for detecting herd infection with small sample size. Most animals have been exposed to Sarcocystis spp., and serological examination cannot differentiate clinical disease from asymptomatic infection.

NECROPSY FINDINGS
Emaciation, lymphadenopathy, laminitis, anemia and ascites are present, but the
most obvious feature is the petechial and ecchymotic hemorrhages throughout the body.\textsuperscript{22} There are also erosions and ulcerations in the oral cavity and esophagus, likely as a result of microvascular damage. Microscopically, schizonts are found in endothelial cells throughout the body, and hemorrhages, lymphocytic infiltration, and edema are seen in heart, brain, liver, lung, kidney, and striated muscle.\textsuperscript{22} Death is probably a result of the severe necrotizing myocarditis that occurs. There is an association between eosinophilic myositis and sarcosporidiosis, but this relationship is not proven in all cases.\textsuperscript{1}

In sheep presenting with neurological disease there may be no findings at gross postmortem, but a non-suppurative encephalomyelitis on histological examination.\textsuperscript{12,14,15} Aborted bovine fetuses show non-suppurative encephalitis, myocarditis, and hepatitis.\textsuperscript{5}

A number of options are available to achieve a definitive diagnosis of the species present, including animal transmission studies, immunohistochemistry, electron microscopy and PCR. Such techniques are seldom required for routine diagnostic cases.

Samples for confirmation of diagnosis
- Histology – formalin-fixed heart, skeletal muscle (several sites, including tongue, masseter muscle) (LM).

Differential Diagnosis
Diagnosis in clinical cases is difficult because of the non-specific signs observed and the widespread prevalence of infection. Sarcosporidiosis is a consideration in the examination of problems of fever and anemia of undetermined origin in cattle and of illness in cattle and sheep. Muscle biopsy may aid in the determination of the presence of infection, but still begs the question of its significance to the clinical disease. The differential diagnoses for abortion in cattle are covered under brucellosis and under brucellosis. Causes of encephalitis and ataxia in sheep are listed under those headings.

TREATMENT
No approved treatment is available, but amprolium or salinomycin may relieve the signs. Amprolium 100 mg/kg given daily from the time of inoculation reduces the severity of infection in experimentally infected calves and sheep,\textsuperscript{12,23} and has been used to control an outbreak in sheep.\textsuperscript{12} Treatment of experimentally infected calves with salinomycin (4 mg/kg BW daily in divided doses for 30 days) reduced the severity of the illness.\textsuperscript{24} Monensin may have a similar ameliorating effect,\textsuperscript{25} but is also suspected of exacerbating muscle lesions.\textsuperscript{10} Oxytetracycline, at very high dose rates, and halofuginone may be effective in acute infections.\textsuperscript{15}

CONTROL
Control is difficult as it involves the separation of carnivores and stock, which is not possible on most farms. However, infection in farm dogs and cats could be avoided if all meat fed to them was thoroughly cooked. Freezing will not destroy the infectivity. Coyotes and wild dogs should be controlled and livestock carcasses not left on fields. Prior exposure to small numbers of pathogenic sarcocysts produces a strong immunity, but there is no vaccine available.

REVIEW LITERATURE

REFERENCES

ETIOLOGY
Neospora caninum, a protozoan parasite of the phylum Apicomplexa in the family Sarcocystidae. N. caninum primarily infects dogs and cattle but has a wide host range and infects all the major domestic livestock species, as well as companion animals and certain wildlife species. Dogs are the only known definitive host with cattle as the major intermediate agricultural animal host. Natural infections are infrequently reported in sheep, goats and deer.\textsuperscript{1} N. caninum is a sporadic cause of encephalomyelitis and myocarditis in several species but its importance is its association with endemic and epidemic abortion in cattle. It is now the common diagnosis for abortion in cattle in most countries. The organism can be isolated, with difficulty, from infected calves.\textsuperscript{2}

EPIDEMIOLOGY
Occurrence
N. caninum was initially associated with abortion in the early 1990s in pastured cattle in Australia and New Zealand, and as a major cause of abortion in large dry-dairy herds in southern California, and dairies in New Mexico, Washington, and Arizona in the United States. Since then, abortion associated with N. caninum has been reported from many countries in cattle under varying management conditions, and has worldwide occurrence.

Abortion may be epizootic or sporadic. In epizootic abortion the number of cows aborting varies. It is usually between 5 and 10%, but up to 45% of cows may abort within a short period. The period of abortion may be a few weeks to a few months. There is no major seasonal occurrence and abortion occurs in both beef and dairy cows.\textsuperscript{3,4} Sporadic abortions occur predominantly in cows that have been infected congenitally and seropositive cows have greater risk for repeat
Part 2: Special Medicine

Chapter 26: Diseases associated with protozoa

Abortion. Seropositivity in herds can be high, but varies widely. One study in dairy herds reports a within herd seroprevalence ranging from 7 to 70% and another in beef herds a within herds seroprevalence ranging from 6.5 to 67%. Seropositive dams have a 3-7 fold higher risk of abortion than seronegative dams.

Methods of transmission

There are two routes of infection of cattle. The dog is identified as the definitive host for *N. caninum* and infection of cattle can occur from the ingestion of oocytes in the dog feces contaminating feed or water. However vertical transmission occurs in both cattle and dogs and vertical (congenital) transmission appears the major route for infection in most cattle.

Live born calves from congenitally infected cows are themselves congenitally infected and the infection is believed to be persistent and lifelong. One study conducted on two dairies found 81% of seropositive cows gave birth to congenitally infected calves. Seroprevalence did not increase with cow age on either dairy, and was stable through the study period. The probability of a calf being congenitally infected was not associated with dam age, dam lactation number, dam history of abortion, calf gender, or length of gestation. Other studies have shown that this route of transmission is highly efficient resulting in infection of 50-95% of the progeny of infected cows.

Congenital infection can result in abortion, the birth of a normal, infected calf, and a infected cow can give birth to a normal, infected calf at one pregnancy and abort in the subsequent pregnancy. The occurrence of infection in some herds can be associated with specific family lines.

Whereas vertical transmission is the major route of infection that leads to sporadic abortions in cattle associated with *N. caninum* epidemiological evidence suggests that postnatal (point) infection is often the cause of outbreaks of abortion. Where of infection are the source of infection many cattle are often exposed and this point source of infection commonly results in outbreaks of abortion. Farm dogs have been shown to have a higher seroprevalence to *N. caninum* than urban dogs suggesting that the disease cycles between cattle and dogs in rural environments.

The importance of postnatal infection versus vertical infection in the genesis of abortion may vary between countries associated with differences in management systems.

Experimental reproduction

Abortion has been produced by experimental challenge of fetuses and pregnant cattle with culture derived tachyzoites of *N. caninum*. Fetal death and resorption or abortion has been reproduced in ewes challenged at 45, 65, and 90 days' gestation, but not 120 days, and lesions resemble those of ovine toxoplasmosis. The disease has also been reproduced experimentally in goats, but the importance and prevalence of this infection in naturally occurring abortions in small ruminants remains to be determined. Contaminated placenta, milk, and colostrum can result in infection of calves under one week of age.

Risk factors

Outbreaks of abortion often appear to be point source infections, but the risk factors, other than probable mass exposure to infected dog feces, are not known. With suspect point source infection the disease in dairy herds frequently occurs as an epizootic, with multiple abortions occurring in a 1 to 2-month period. Severely autolytic fetuses are aborted in the 5th-7th month of pregnancy in most reports, but earlier abortions are recorded in some, and the agent has been associated with outbreaks where the gestational age of fetal loss has ranged from 3 to 8.5 months. Heifers may abort earlier in pregnancy than older cows.

Endemic abortion is more likely associated with the presence of congenitally infected cattle in the herd, which are at high risk of aborting, particularly in the initial pregnancy and in the pregnancy during the first lactation. Cows that have aborted have higher risk for abortion in subsequent pregnancies, but the risk decreases with each subsequent pregnancy. The true frequency of repeat abortions is unknown because cows may be culled for abortion.

It has been postulated that immune-suppression resulting from concurrent infection with agents such as BVD virus may increase the risk for infection with *N. caninum* and precipitate outbreaks of abortion. Concurrent *N. caninum* and BVD infections in aborted fetuses have been observed in some studies and one study has found a significant association between abortion and cows with antibodies to both *N. caninum* and BVD. Others have found no association and whereas concurrent BVD infection might be a risk factor in some outbreaks, it is not in all.

Economic importance

Economic loss is occasioned by the direct cost of abortions and the indirect costs associated with establishing the diagnosis and re-breeding or replacement costs. Seropositivity is also associated with increased risk of stillbirth and increased risk of retained placenta.
epidemiological studies suggest that congenital infection does not necessarily have a detrimental effect on calf health and survival.28

N. caninum infection has been demonstrated in the nervous system of a horse with progressive depletion, followed by sudden onset of neurological disease with paraplegia.29 It appears a rare cause of neurological disease in horses but should be considered in the differential diagnosis of equine protozoal myeloencephalitis.

**CLINICAL PATHOLOGY**

Serological examination is with the indirect antibody fluorescent test (IFAT), or by ELISA, and there is good agreement between the two tests. ELISA tests based on recombinant protein have higher sensitivities and specificities than that based on whole-tachyzoite lysates.30 The IFAT is highly sensitive and specific for detection of maternal infection31 and is commonly used. One study compared IFAT titers in maternal sera from 40 cows whose fetuses had been examined for neosporosis by immunohistochemistry. Of the 22 confirmed cases, 21 cows had titers of >1 in 640, whereas only one of the 18 negative cases had a titer of this magnitude.32 The persistence of titers following infection is uncertain, and they may fluctuate during pregnancy. A positive titer in a cow that has aborted indicates exposure but not causality. Recently, IgG avidity patterns have been used to determine the duration of infection.33,34

Diagnosis is also made by the detection of antibody in fetal pleural fluid or sera,35 and IFAT antibody has been found in the sera of from 50 to 65% of immunohistochemistry-confirmed cases of neospora infection, but not in fetuses under 4 months of gestational age.36,37 Antigen can also be detected by PCR.38

**NECROPSY FINDINGS**

Gross findings are of autolysis. The brain may be autolysed, but should still be submitted for examination along with heart, liver, and placenta if available. Histological lesions are of multifocal encephalitis, myocarditis, and periportal hepatitis. Liver lesions may be more prominent in epizootic abortions. Immunohistochemistry using anti- N. caninum serum is used to identify tachyzoites in tissues, and the brain is the organ with the highest detection rate.39 Immunohistochemistry is specific, but insensitive, in diagnosing fetal neosporosis, and maternal serology should be used in conjunction

**TREATMENT**

There is no treatment that can be used to curtail an ongoing abortion epidemic and possible drug therapies are generally not considered an option because of likely unacceptable milk and meat residues and withdrawal problems.9

**DIFFERENTIAL DIAGNOSIS**

Serology using IFAT can confirm infection in individual cows. Because of the high prevalence of infection, and the occurrence of congenital infection, care must be taken in extrapolating the results of a single positive diagnosis to problems of abortion. The high rate of natural congenital infection means that evidence of infection in an aborted fetus is not proof of causation of abortion, and fetal examination should be coupled with serological examination of aborting and non-aborting animals in the herd for statistical differences.

- Other causes of abortion in cattle
- Weak calf syndrome.

**CONTROL**

All efforts should be made to exclude the possibility of dog fecal contamination of cattle feed and water and of the grazing environment.30 Placenta, aborted fetuses, and dead calves should be removed and disposed of so that the definitive host and cattle cannot get access to them. Congenitally infected cows are at high risk for abortion, and abortion rates in infected herds can be substantially reduced by culling these animals.34,40 Congenitally infected calves can be identified by serology on precolostral blood samples and culled at a young age. If precolostral blood sampling is not feasible, examination of sera at 6 months of age will determine infected calves, positive titers indicating either congenital infection or postnatal infection.41 Animals purchased into the herd should be seronegative.

It is possible that strategic therapy of pregnant cows with an appropriate anti-protozoal drug could abort the infection. This could be effective in beef cattle, but would probably not be legal, or appropriate, in lactating dairy cattle.

Whereas evidence for increased risk for neospora abortion due to immunosuppression resulting from concurrent infection with BVD virus is equivocal control of BVD infections should be a component of control programs for neosporosis.

A killed tachyzoite vaccine has been approved in the United States for use in pregnant cows and is available commercially. At present there are no controlled studies in the United States on its efficacy in mitigating the effects of bovine neosporosis in dairy cattle. A field trial in dairy herds in Costa Rica measuring abortion as the outcome showed a reduction in the incidence of abortion.42 A study in growing beef cattle showed no significant effects between vaccinated and control animals in cumulative average daily gain or in food conversion efficiency.43 Studies in sheep have shown that vaccination significantly reduces fetal loss in experimentally infected ewes. However, they showed that there was little protection against vertical transmission of N. caninum to the fetuses.45,46

Vaccination of dairy cattle may interfere with herd test and cull policy.

28. Neosporosis
CRYPTOSPORIDIOSIS

**Synopsis**

**Etiology** Cryptosporidium parvum bovine genotype 2 and C. andersoni.

**Epidemiology** Infection common in ruminant neonates. May cause diarrhea, especially if there is intercurrent infection with other enteropathogens, nutritional, or environmental stress.

**Clinical findings** Malabsorption-type diarrhea.

**Clinical pathology** Oocysts in feces demonstrated by immunofluorescent assay.

**Lesions** Villous atrophy.

**Diagnostic confirmation** Demonstration of lesions and organism.

**Treatment** Supportive. Halofuginone or paromomycin if approved.

**Control** Hygiene and management to ensure passive transfer of colostral antibodies and minimization of infection pressure.

**ETIOLOGY**

Cryptosporidium are protozoan parasites in the Phylum Apicomplexa. Currently, up to 14 species of Cryptosporidium, infecting mammals, fish, and birds, have been proposed but only two of these are of importance to agricultural animals. These include *C. parvum* which infects many different hosts including cattle, swine, horses, and small ruminants, and the calf genotype of *C. muris*, now called *C. andersoni*, which infects cattle. *C. parvum* has two distinct genotypes known as human genotype 1 (also known as *C. hominis*) and bovine genotype 2. Both genotypes are capable of causing disease in humans. Livestock and horses are not commonly infected with genotype 1, although recently infections have been experimentally produced in lambs and piglets and mixed infections with genotypes 1 and 2 have been observed in calves.

Cryptosporidium parvum is a common infection in young ruminants and is found in many species of mammals including humans. There has been controversy about the role of *C. parvum* as a causative agent of diarrhea because infection can be found in normal healthy animals. However, it is considered a significant cause of varying degrees of naturally occurring diarrhea in neonatal farm animals. Most commonly, the agent acts in concert with other enteropathogens to produce intestinal damage and diarrhea.

**EPIDEMIOLOGY**

**Occurrence and prevalence** Cryptosporidiosis has been recognized worldwide, primarily in neonatal calves, but also in lambs, goat kids, foals, and piglets. Many studies report prevalence of infection but this does not imply clinical disease.

**Calves**

Infection is common in calves but reported prevalence rates of *Cryptosporidium* in feces vary widely. Prevalence ranging from 1.1% in a random sample of adult cattle feces in California to 79% in symptomatic calves in Maryland, USA have been reported. Cryptosporidia have been detected in 70% of 1 to 3-week-old dairy calves based on a single examination of feces. A single sampling in a nationwide survey of 7369 calves on 1103 farms in the United States found infection on 59.1% of farms, and in 22.4% of calves. Daily sampling of calves in the first 4 weeks of life show higher rates of infection and a period prevalence of infection as high as 100%. There is also high site prevalence.

A 6 year longitudinal study, on a lowland farm in the United Kingdom, of patterns of fecal excretion of *C. parvum* in beef cattle, dairy cows, home bred and purchased calves, lambs, rodents in the farm building environment and in the pastures, showed that the parasite was endemic and persistently present in all animal species tested. It found that patterns of infection were variable and that short-term or point prevalence sampling would be unlikely to provide a representative picture of infection rates. Prevalence rates and oocyst numbers in feces were highest in yearling calves. Infection can be detected as early as 5 days of age, with the greatest proportion of calves excreting organisms between days 9 and 14. This is also the period of greatest intensity of excretion of the organism in the feces of individual calves.

Infection of the calf is followed by the development of resistance to reinfection, and oocyst excretion is less common and intermittent in older and adult cattle, although high excretion rates are found in adult cattle in some herds.

Most prevalence studies have found little association between infection and diarrhea, but there are many reports that associate infection in calves with diarrhea occurring between 5 and 15 days of age.

Sheep and goats

*C. parvum* is also a common enteric infection in young lambs and goats, and diarrhea can result from a monoinfection, but more commonly is associated with mixed infections. The age pattern of infection and excretion of the organism is similar to that in calves. Infection can be associated with severe outbreaks of diarrhea, with high case fatality in lambs from 4 to 10 days of age and goat kids from 5 to 21 days of age.

Pigs

Cryptosporidial infection in pigs occurs over a wider age range than in ruminants and has been observed in pigs from 1 week of age through to market age. In a retrospective study of piglets submitted to a diagnostic laboratory over a 4-year period, cryptosporidia were detected histologically in 5.2% of about 3500 piglets. Infection is most common between 6 and 12 weeks of age. The majority of infections are asymptomatic, and the organism does not appear to be an important enteric pathogen in this species, although it may contribute to postweaning malabsorptive diarrhea.

Foals

Cryptosporidial infection in foals appears less prevalent and occurs at a later age than in ruminants, with excretion rates peaking at 5-8 weeks of age. Infection is not commonly detected in yearlings or adults. Most studies indicate that cryptosporidiosis is not a common disease in foals, and infections in immunocompetent foals are usually subclinical. Diarrhea is recorded in foals from 5 days to 6 weeks of age including a report of an outbreak lasting one month where 9 of 30 foals aged between 4 days and 3 weeks of age were affected with a case fatality rate of 33%. Persistent clinical infections occur in Arabian foals with inherited combined immunodeficiency.

Farmed deer

Cryptosporidiosis is also recorded in young deer and can be a cause of diarrhea in artificially reared orphans. Infection has also been recorded in red deer calves dying at 24–72 hours of age following a syndrome of severe weakness and depression accompanied by a terminal uremia.

**Source of infection and transmission** Experimental infections have shown that a small number of oocysts are required for infection. The replicative cycle in the
intestine amplifies a minor infective dose and studies in gnotobiotic lambs indicate a minimum infective dose as low as one oocyst. The source of infection is feces which contain oocysts that are fully sporulated and infective when excreted. Large numbers are excreted during the patent period in calves resulting in heavy environmental contamination. Transmission may occur directly from calf to calf, indirectly via fomite or human transmission, from contamination in the environment or fecal contamination of the feed or water supply. Infection into the environment of newborn animals, and an increase in contamination of their immediate environment occurs as the result of a periparturient rise in the fecal excretion of oocysts by the dam. This has been recorded in ewes, in a beef cattle herd where the rate of infection and the number of oocysts in cattle feces increased significantly at one week post calving and in some dairy herds. Genotype 1 of Cryptosporidium parvum is not host-specific and infection from other species, such as rodents or farm cats, contaminating calf feeds, is also possible.

**Risk factors**

The factors that make animals susceptible to infection and that predispose infected animals to develop clinical disease are not well understood. Disease in agricultural animals associated with infection with Cryptosporidium is associated with infection with C. parvum and there is little evidence that infection with C. andersoni is associated with disease. Commonly, other enteric infections are present where there is disease attributed to Cryptosporidium. The site of infection with C. parvum is on the enterocyte where it results in cell damage, loss of brush border enzymes and a reduction of villous surface area.

**Pathogen risk factors**

Oocysts are resistant to most disinfectants and can reportedly remain viable for about 18 months in a cool, damp or wet environment, can survive for several months in soil and slurry but are susceptible to desiccation and temperatures above 60°C. The infectivity of the oocysts can be destroyed by ammonia, formalin, freeze-drying and exposure to temperatures below 0°C (32°F) and above 65°C (149°F). Ammonium hydroxide, hydrogen peroxide, chlorite dioxide, 10% formal saline and 5% ammonia are effective in destroying the infectivity of the oocysts. The infectivity of oocysts in calf feces is reduced after 1–4 days of drying.

Concurrent infections

Concurrent infections with other enteropathogens, especially rotavirus and coronavirus, are common and epidemiological studies suggest that diarrhea is more severe with mixed infections. The rates of single and mixed infections vary with different studies. In general, mixed infections are most common, but cryptosporidial infection can be significant in its own right. For example, in two studies involving diarrheic calves submitted to diagnostic laboratories, cryptosporidia were the only pathogens isolated in 51% and 55% of the cases, while in 25% and 39% of cases the protozoan agent was found in combination with rotavirus and/or coronavirus. Immunologically compromised animals are more susceptible to clinical disease than immunocompetent animals, but the relationship between disease and failure of passive transfer of colostral immunoglobulins is not clear. The disease can be reproduced in both colostrum-deprived and colostrum-fed calves and, in the field, clinical disease can occur in calves and foals with adequate passive transfer of colostral immunoglobulins. However, the shedding of the organism has been observed to be higher in calves with low absorptive efficiency of IgG from colostrum and low serum IgG concentrations.

**Season**

In one series of observations there was a tendency for the prevalence of infection to be higher during the winter months of the year when the calves were confined, which suggests a build-up of contamination, but seasonal difference in prevalence is not marked and clinical disease can occur at all seasons.

**Interactions**

Case fatality rates in cryptosporidiosis are generally low unless there are other complicating factors. In addition to concurrent infections, these include energy deficits from inadequate intake of colostrum and milk, and chilling from adverse weather conditions.

**Age**

Age-related resistance, unrelated to prior exposure, has been observed in lambs but not calves. Infection results in the production of parasite-specific antibody, but both cell-mediated and humoral antibody are important in protection, as well as local antibody in the gut of the neonate.

**Experimental reproduction**

The disease has been reproduced in colostrum-deprived calves, lambs and kids, in many studies.

**Zoonotic implications**

Infections in domestic animals and pets may be a reservoir for infection of susceptible humans. In humans, cryptosporidium is considered to be a relatively common non-viral cause of self-limiting diarrhea in immunocompetent persons, particularly in children. In symptomatic immunocompetent patients, cryptosporidiosis most commonly presents with diarrhea that can lead to rapid weight loss and dehydration and require parenteral fluid therapy. The disease is usually self-limiting, symptoms normally lasting between 3 and 12 days. In immunologically compromised persons, clinical disease may be severe. This is particularly serious in human patients with acquired immune deficiency syndrome. The infection is transmitted predominantly from person to person, but direct infection from animals, and indirect water-borne infection from contamination of surface water and drinking water by domestic or wild animal feces can also be important. Animal manures and slurry may contain C. parvum and there is potential for contamination of the food chain as a result of run-off into adjacent surface waters or from direct application of the untreated wastes to crops. Recently, this risk for human infection has been a cause of public concern but this concern has been somewhat mitigated by the recognition that the cattle genotype does not infect humans.

Direct animal contact can result in human infection where there is hand to mouth transmission and infection and disease is recorded in veterinary students and is a concern for children at fairs, petting zoos and in educational visits in farm settings. Cryptosporidiosis is one of a number of zoonotic infections that have recently emerged in these settings. The apparent increase in prevalence of these infections could be due to the general movement of populations from rural to urban communities and the consequent removal from early exposure to farm animal-derived zoonotic agents. Equally, it could result from better detection and reporting by public health authorities. Regardless, the risk for transmission of zoonotic agents associated with petting zoos, farm animal exhibits, and fairs etc, is real and veterinarians are increasingly asked for advice on this issue. This can be in association with an official capacity as a fair veterinarian or in consultation with farm owners, who desire to bridge the increasing estrangement of urban populations to farm activities by allowing farm tours which frequently involve younger ages and more susceptible humans.

Animal handlers on a calf farm can be at high risk of diarrhea due to cryptosporidiosis transmitted from infected calves, and immunocompromised people should be restricted from access to young
animals, and possibly from access to farms.

**PATHOGENESIS**
The life cycle of Cryptosporidium consists of six major developmental events. Following ingestion of the oocyst there is excystation (release of infective sporozoites), merogony (asexual multiplication), gametogony (gamete formation), fertilization, oocyst wall formation, and sporogony (sporozoite formation). Thus the oocysts of Cryptosporidium spp. can sporulate within the host cell, in contrast to the oocysts of Eimeria and Isospora spp., which do not sporulate until they are passed from the host, and they are infective when passed in the feces. The infection persists until the immune response of the animal eliminates the parasite. In natural and experimentally produced cases in calves, the cryptosporidia are most numerous in the lower part of the small intestine and occasionally in the cecum and colon. The prepatent periods range from 2 to 7 days in calves, and from 2 to 5 days in lambs. Oocysts are usually passed in the feces of calves for 3–12 days.

The intracellular stages of the organism are within a parasitophorous vacuole, which is confined to the microvillous region of the host cell. The cryptosporidia appear free in the lumen of the intestine and attached to the microvilli of the villous epithelial cells. The parasitophorous envelope of the trophozoites and schizonts are derived from the microvilli, and the intracellular location of the organism is confined to fusion of the organism, with the apical cytoplasm of the epithelial cells and their enclosure by host membranes. Thus the organism is intracellular but extracytoplasmic.

The pathogenesis of the diarrhea is unknown, but the varying degrees of villous atrophy suggest that digestion and absorption may be impaired, resulting in diarrhea. The experimental inoculation of gnotobiotic calves with a monoinfection of Cryptosporidium species treated with peracetic acid to destroy other possible enteropathogens results in lesions of villous atrophy and diarrhea, which indicates that the organism can cause intestinal lesions without concurrent infection with other enteropathogens. There is also evidence of hyperplastic crypt epithelium, which along with damaged villous epithelium and atrophic villi indicates that the lesions develop as a result of accelerated destruction or loss rather than decreased production of epithelial cells.

**CLINICAL FINDINGS**
There are no clinical findings characteristic of diarrhea due to infection with C. parvum in calves. In general, calves are usually 5–15 days old and have a mild to moderate diarrhea which persists for several days regardless of treatment. The age at onset is later, and the duration of diarrhea tends to be a few days longer, than the diarrheas associated with rotavirus, coronavirus, or enterotoxigenic *Escherichia coli*. Feces are yellow or pale, watery, and contain mucus. The persistent diarrhea results in marked loss of body weight and emaciation in some cases. In most cases, the diarrhea is self-limiting after several days. Varying degrees of apathy, reduced feed intake and dehydration are present. Only rarely does severe dehydration, weakness and collapse occur, in contrast to other causes of acute diarrhea in neonatal calves. Case fatality rates can be high in herds with cryptosporidiosis when the calf feeder withholds milk and feeds only electrolyte solutions during the episode of diarrhea. The persistent nature of the diarrhea leads to a marked energy deficit in these circumstances and the calves die of inanition at 3–4 weeks of life. This syndrome may be particularly common in the winter months where there is additional cold stress affecting energy requirements.

In the experimental disease in calves, depression and anorexia are the earliest and most consistent clinical findings. Feed intake is reduced and, combined with the persistent diarrhea over several days, may cause emaciation. Recovery occurs between 6 and 10 days after the onset of diarrhea.

In the experimental disease in lambs and kids, depression, diarrhea, and reduced feed intake are common and recovery occurs within a few days. More severe clinical manifestations have been observed in the field in lambs subject to environmental cold stress and those that are energy deficient due to an inadequate intake of colostrum.

**CLINICAL PATHOLOGY**

Diagnosis of cryptosporidiosis is traditionally based on the detection of fecal oocysts. The oocysts can be detected in the feces by examination of fecal smears with certain stains, by fecal flotation, or by immunollogically assisted methods. Current diagnostic techniques used in most clinical laboratories include the immunofluorescent assay visualization of fecal oocysts. It has been suggested that, if the diarrhea is associated with cryptosporidia, the feces should contain 10^5–10^7 oocysts per mL of feces. The oocysts are small (5–6 μm in diameter), relatively non-refractile, and difficult to detect by normal light microscopy. They are readily detected by phase-contrast microscopy. The demonstration of oocysts concentrated from fecal samples is by centrifugal flotation in high specific-gravity salt or sugar solutions.

The modified Ziehl–Neelsen is a simple and rapid procedure well suited for large-scale routine diagnosis of cryptosporidia. An immunofluorescence technique on fecal smears is available, as are immunoassays.

**NECROPSY FINDINGS**
Varying degrees of dehydration, emaciation, and serous atrophy are present in calves that have had persistent diarrhea for several days. There is atrophy of villi in the small intestine. Histologically, large numbers of the parasite are embedded in the microvilli of the absorptive enterocytes. In low-grade infections, only a few parasites are present, with no apparent histological changes in the intestine. The villi are shorter than normal, and there is crypt hyperplasia and infiltration with a mixture of inflammatory cells.

**Samples for confirmation of diagnosis**
- **Parasitology** – feces (microscopic examination, ELISA, FAT)
- **Histology** – formalin-fixed jejenum, ileum (several sites), colon.

**DIFFERENTIAL DIAGNOSIS**
The disease must be differentiated from other common infectious diarrheas in calves, which are covered in the section on acute undifferentiated diarrhea.

**TREATMENT**

**Specific therapy**

Several different types of antiprotozoal drugs and antimicrobials have been evaluated with no therapeutic effect. The exceptions are halofuginone and paromomycin.

Halofuginone is reported to markedly reduce oocyst output and the severity of diarrhea and/or mortality in infected calves and naturally and experimentally infected calves. Therapy with this drug significantly reduced the severity of diarrhea and dehydration compared with sulfadimidine therapy in calves and a randomized double blind trial in calves has shown a significant prophylactic effect when given for 7 days from 1 day of age. Preliminary studies suggest that an oral dose of 60–125 μg/kg BW daily for 7 days will protect against clinical disease and will markedly reduce oocyst excretion, but will allow some intestinal infection and thus the development of immunity. The results of these studies suggest that the drug prevents reinfection of the gut by sporozoites and recycling merozoites.

**Paromomycin sulfate** given orally at a dose of 100 mg/kg BW daily for 11
consecutive days from the second day of age proved successful in preventing natural disease in a controlled clinical field trial in goat kids and to reduce but not completely prevent diarrhea in infected lambs.

**Supportive therapy**

Affected calves should be supported with **fluids and electrolytes**, both orally and parenterally as necessary until spontaneous recovery occurs. Cows' whole milk should be given in small quantities several times daily to optimize digestion and to minimize loss of body weight. It is important to **continue to feed milk** to the full level.

**REVIEW LITERATURE**

**ETIOLOGY**

The disease is difficult to control. The rational approach to prevention is to **minimize transmission** between the source of the organism and neonatal farm animals, and between the animals. Reducing the number of oocysts ingested may reduce the severity of infection and allow immunity to develop. Calves should be born in a clean environment and adequate amounts of colostrum should be fed at an early age. Calves should be kept separate without calf-to-calf contact for at least the first 2 weeks of life, with strict hygiene at feeding. Disinfectants detailed above should be employed in hygiene.

Diarrheic calves should always be **isolated** from healthy calves during the course of the diarrhea, and for several days after recovery. Sick calves are commonly treated by the same person who is likely to be carrying the organism in feces by phase microscopy or immunofluorescent antibody.

variants from mammals are all placed in the one species and the genotypic designation of *G. duodenalis* is evolving, with groups, assemblages and genotypes all used. Cattle are susceptible to infection with genotypes in the zoonotic genotype Assemblage A, which infect several different animal species, and the livestock genotype, Assemblage E, which appears restricted to hoofed animals.

The organism develops in the small intestine where it multiplies by binary fission on the surface of the intestinal mucosa in the trophozoite stage and is excreted in feces as a cyst.

**EPIDEMIOLOGY**

**Occurrence**

Giardial infection, as opposed to disease, has been reported from most continents and has been identified in all of the common agricultural animals. There is a wide variation in reported prevalence between regions, which probably reflects sampling strategies and detection methodologies. Excretion of giardial cysts may be continual or intermittent in young animals. Most prevalence studies have been in calves, and reported point prevalence infection rates in different countries range from 1 to 100%, with the majority of studies showing between 20% and 80% of calves infected and high farm prevalence rates.

A similar large range is evident in more limited studies in lambs, kids, foals, and piglets. Longitudinal studies of excretion patterns in grazing beef cattle, feedlot cattle, dairy cattle, calves, and foals show infection rates approaching 100%, but hygiene in management practices can affect the age at exposure and the exposure intensity, and can influence infection dynamics. The high and early infection rates in calves and lambs compared with other livestock species are probably a reflection of this. Pigs reared on wire floors are infected later in life than pigs reared on porous concrete floors.

The prevalence of infection is higher in calves left with their dams to nurse colostrum for 3 days than in calves removed from the dam at birth to individual housing and fed colostrum by nipple bottle. The prevalence of infection is higher in calves left with their dams to nurse colostrum for 3 days than in calves removed from the dam at birth to individual housing and fed colostrum by nipple bottle.

**Source of infection**

Young animals are the primary source of infection, infection being transmitted through the oral–faecal route. High excretion rates and excretion intensities in young animals result in the contamination of the environment and infection via fomites. The dam is also a source of infection for the young. Relaxation of immunity in the young of all livestock species is probably a reflection of this. Giardia cyst excretion has been reported from most continents and new infections can result from exposure to fomites. Experimental reproduction following experimental challenge in calves, there is a prepatent period of 7–8 days and the calves subsequently excrete large numbers of cysts for periods varying from 60 to 112 days without evidence of clinical disease. Infection of 6-week-old specific-pathogen-free (SPF) lambs with *Giardia* trophozoites has resulted in the occurrence of episodes of diarrhea and soft feces that are temporally associated with the detection of *Giardia* cysts in feces. When compared with controls, infected lambs had reduced rate of gain without reduction in food intakes and took longer to reach market weight.

**Economic importance**

Evidence for a significant pathogenic and economic importance for the majority of giardial infections in agricultural animals is not convincing.

**Zoonotic implications**

The majority of giardial infections in cattle are with the livestock-associated assemblage with a small proportion of infections with the zoonotic Assemblage A. Contact with farm livestock is one risk factor for disease in humans. The is considerable concern in public health circles that infection of humans could also occur via water bodies receiving agricultural effluent and pasture runs, leading to drinking water contamination. There is also concern for fecal dispersion of *Giardia* in back country watersheds from pack animals.

**PATHOGENESIS**

Ingested cysts release trophozoites, which multiply and colonize the small intestine. These adhere to the villi of the small intestine by means of a suction disc on the trophozoite's ventral surface to result in inflammatory cell infiltration, villus atrophy, a reduced villus to crypt ratio and a reduction in brush border disaccharidase enzymes. Disease, if it occurs in domestic animals, is believed to result from nutrient malabsorption and consequent diarrhea.

**CLINICAL FINDINGS**

There are several reports that detail the demonstration of giardial infection in individual animals with a chronic, malabsorptive type of diarrhea, and most imply an association with diarrheal disease. Most of these are in young animals at an age when both undifferentiated diarrhea and *Giardia* cyst excretion are common, but the evidence for a causal association is not convincing. There are also a number of studies on the incidence of infection in animals that comment that infection is not accompanied by evidence of clinical disease.

**Necropsy findings**

Ferrets and in some small intestine and and are non-specific. Reported changes are an increase in intraepithelial lymphoto
cytes in the jejunal, with moderate to severe diffuse inflammation, villus atrophy, crypt distortion and a reduction in the villus to crypt ratio. Trophozoites are present in the mucosa and mucosal scrapings of the small intestine.

TREATMENT AND CONTROL
Giardia infections in agricultural animals have been successfully treated with nitroimidazoles at a dose of 50 mg/kg BW daily for 5 days and is also susceptible to furazolidone, but both drugs are illegal for use in food animals in many countries. The benznidazoles, albenazole (20 mg/kg BW daily for 3 days) or fenbendazole (10 mg/kg BW daily for 3 days) are effective in eliminating infection in calves. The 3-day course is required for effective elimination and some calves become reinfected following treatment. Continuous therapy by the incorporation of fenbendazole in a free choice mineral to a concentration of 0.55% was not effective in reducing giardial infection in grazing steers.

In the absence of an association with significant disease, control procedures for giardiasis have not been developed for livestock. Those described for reduction of exposure in the section on undifferentiated diarrhea are appropriate.

BESNOITIOSIS (ELEPHANT SKIN DISEASE)

Synopsis

ETIOLOGY
Intermediate host-specific tissue cysts of Besnoitia besnoiti, B. caprae, and B. Bennettii.

EPIDEMIOLOGY
Endemic disease in some tropical and subtropical areas with high morbidity and low mortality. Rare disease elsewhere. Definitive host not known. Possible insect transmission of disease in cattle and goats.

CLINICAL FINDINGS
Anasarca, alopecia, hyperpigmentation and scleroderma and infertility.

Inspiratory dyspnea and loss of condition
Pin-point nodules (cysts) on the sleral conjunctiva, nasal, pharyngeal, and laryngeal mucosa.

Lesions
Parasitic cysts in dermis, subcutaneous, and other fascia.

Diagnostic confirmation
Demonstration of bradyzoites in skin biopsy or scleral conjunctival scrapings.

Treatment and control
Little information available.

Besnoitiosis is a parasitic disease of cattle, goats, horses, and certain wild animals, and infections in the chronic cystic stage can result in severe production loss.

ETOLOGY
Besnoitia are coccidian parasites in the family Sarcocystidae. The life cycle involves a definitive host and an intermediate host.

There are seven classified species, which of which three occur in domestic livestock. These are B. besnoiti in cattle, B. caprae in goats, and B. bennetti in horses, donkeys, and mules.

The other four Besnoitia species infect wildlife species. Cats are the definitive host for some Besnoitia infecting wildlife, but the definitive host(s) for the three domestic livestock species are unknown.

Recent studies suggest that B. besnoiti and B. caprae are genetically identical, that they also have identical bradyzoite ultrastructure and that they may not be separate species.

EPIDEMOLOGY
Occurrence
Besnoitiosis in livestock occurs as outbreaks in some tropical and subtropical regions and sporadically in other areas. In endemic areas, the disease can affect a large proportion of the herd and cause significant economic loss.

Bovine besnoitiosis is recorded in the African continent, southern Europe, South America, Israel, Asia, and the Soviet Union; caprine besnoitiosis in Kenya, Uganda, Iran, and Kazakhstan; equine besnoitiosis in north and east Africa.

Risk factors
Besnoitia are relatively host specific. B. besnoiti infects cattle and in Africa also infects goats and wild ruminants. The Kenyan species of B. caprae does not infect cattle or sheep.

The natural means of transmission is not known, but is presumed to be by ingestion of oocysts from the definitive host(s). Infection with B. besnoiti and B. caprae can be transmitted experimentally with endozoites and bradyzoites, and mechanically by infections or biting flies.

Outbreaks of clinical disease in cattle or goats occur in fly seasons and it is postulated that biting insects may be important vectors. Transmission via semen from infected males is also postulated.

Economic importance
B. besnoiti is an economically important parasite of cattle in Africa and Israel. Attack rates can be high and although mortality is generally low it can approach 10% in the chronic stages. There is loss of condition and fertility of males in both cattle and goats can be significantly impaired from chronic scrotal skin lesions. Skins have no value for tanning. Equine besnoitiosis appears to have rare occurrence.

PATHOGENESIS
Following infection of the intermediate host, the endozoites (tachyzoites) proliferate in macrophages, fibroblasts, and endothelial cells, causing vasculitis and thrombosis, particularly in capillaries and small veins of the dermis, subcutis, and testes. They then mature to form bradyzoite cysts (cytozoites) within fibroblasts. Replication is accompanied by cellular destruction and the release of inflammatory mediators resulting in anorexia, lethargy, testicular degeneration, generalized edema of the skin, alopecia, and scleroderma.

Besnoitia cysts form in high numbers in the dermis and subcutaneous tissue. Inspiratory dyspnea is associated with infection in the upper respiratory tract.

CLINICAL FINDINGS
Bovine besnoitiosis

Typical signs occur in two stages: the acute anasarca stage associated with the proliferation of endozoites and the chronic scleroderma stage associated with cyst formation.

Acute stage
There is fever, an increase in pulse and respiratory rates, and warm, painful swellings appear on the ventral aspects of the body, interfering with movement. There is also generalized edema of the skin. The superficial lymph nodes are swollen, diarrhea may occur, and pregnant cows may abort. Laceration and an increased nasal discharge are evident and small, whitish, elevated macules may be observed on the conjunctiva and nasal mucosa. The nasal discharge is serous...
initially, but becomes mucopurulent later and may contain blood.

Chronic stage
As the disease becomes more chronic, the skin becomes grossly thickened, corru­gated, and there is alopecia. A severe dermatitis is present over most of the body surface. Affected bulls often become sterile for long periods, especially if the scrotal skin is affected. Cystic stages of the Besnoitia have been found in vascular lesions in the testes of affected animals and may be a major contributor to the sterility. Cysts on the scleral conjunctiva are considered to be of particular diagnostic significance. The case fatality rate is about 10% and the convalescence in survivors is protracted over a period of months. In endemic areas, the signs that attract clinical attention are alopecia, and severely thickened and wrinkled skin which is often thrown into folds around the neck, shoulder, and rump region and the carpel and tarsal areas. Small, subcutaneous, seed-like lumps can be palpated. In cattle, infections of the teat skin may result in lesions around the mouth in suckled calves.

Caprine besnoitiosis
The acute stage is not commonly seen in goats, and the disease presents like the chronic stage in cattle,5,8 with dyspnea and cutaneous lesions. The cutaneous lesion is a chronic dermatitis of the legs, particularly the carpal and tarsal areas, and the ventral surface of the abdomen. It varies from mild thickening with superficial scaling to marked thickening with hyperpigmentation and a serious discharge. The hair is sparse.

Equine besnoitiosis
Horses may show exercise intolerance, nasal discharge, and inspiratory dyspnea. Skin lesions, like those in cattle and goats, are present on the ventral abdomen and legs or the whole body surface.8,10 Pinpoint white nodules can be seen by endoscopy on the soft palate, pharynx, and larynx.10

CLINICAL PATHOLOGY
There is little information on hematology and blood chemistry. Hypergammaglobulinemia has been reported in one horse.10 Bradyzooite cysts containing a number of banana or spindle-shaped spores can be detected in scrapings or sections of skin, or scleral conjunctival scraping.4 Ear-tip biopsies are commonly used in surveys of goats, and many infected animals show no clinical signs of infection. Serum antibodies to Besnoitia spp. are identifiable by an indirect immunofluorescence technique and by an ELISA, but the tests have only moderate sensitivity.11,12

NECROPSY FINDINGS
Necropsy lesions in cattle with the severe form of the disease are characterized by widespread vascular lesions and secondary lesions in skeletal and heart muscle, and lungs. The parasite is evident in lesions on histological examination. In the chronic form in goats, multiple grayish-white cysts are found in the subcutis of the neck, limbs, thoracic region, and the intermuscular fascia. Cysts are also present in the nasal mucosa, larynx, soft palate, and trachea, and the scrotum and testes of males.1,5

DIAGNOSTIC CONFIRMATION
The most efficient and cost-effective method of diagnosis of clinical disease is the demonstration of Besnoitia bradyzoites in skin biopsy smears or scleral conjunctival scrapings.6

TREATMENT AND CONTROL
There is little information on treatment. Clinical cure of a donkey with a 9-month history of chronic skin disease is reported following prolonged oral administration of trimethoprim–sulfamethoxazole.8 Animals should receive supportive therapy and be treated symptomatically for enteritis or dermatitis.

A vaccine containing Besnoitia besnoiti, grown on tissue culture, and originally isolated from blue wildebeest, has been used to vaccinate cattle. A durable immunity to the clinical form of the disease was produced in 100% of vaccines, but subclinical infection at a low level did occur.13

TOXOPLASMOSIS

Clinical findings
Abortion and stillbirths in ewes is the major veterinary manifestation, minor manifestations in all species are encephalitis, pneumonia, and neonatal mortality. Major importance as a zoonosis from organisms in meat.

CLINICAL PATHOLOGY
Serological tests, which vary in sensitivity and specificity.

Lesions
Granulomatous lesions in organs of all species, with abortions, placentitis, and focal necrotic lesions in brain, liver, and kidney of aborted fetus.

Diagnostic confirmation
Demonstration of organism. PCR.

Treatment
Not usually indicated. Sulfamethazine and pyrimethamine in abortion outbreak.

Control
Reduce exposure to oocysts. In pregnant sheep, prophylactic feeding of monensin or decoquinate, vaccination.

ETIOLOGY
The causative agent Toxoplasma gondii is a systemic coccidian, a universal parasite, a sporozoan, and a member of the suborder Eimeriina. It is a specific parasite of the definitive host (members of the Felidae family), but has a wide range of intermediate hosts. There are three clonal lineages designated type I, II, and III which differ in virulence and epidemiological pattern. Strains isolated from animals are mostly genotype III.1

T. gondii has three infective stages:
1. Tachyzoites - the rapidly multiplying form of the parasite present during the acute stage of infection in the intermediate host
2. Bradyzoites - present in the tissue cysts
3. Oocysts (containing sporozoites) - present only in cat feces.

Oocysts are the infective stage of importance in farm animals, and the only environmental infective stage for herbivores. Oocysts excreted in the feces of cats can survive in soil for many months and are ingested by the intermediate (livestock) host, and the parasite invades tissues to produce tissue cysts. The invasion can include the fetus. An inoculum containing as few as ten oocysts can be infective for goats. Tissue cysts in the intermediate host cause damage to the nervous system, myocardium, lung tissue, and placenta. Bradyzoites in animal tissues are a source for toxoplasmosis in humans and pigs.

EPIDEMIOLOGY
Occurrence
Toxoplasmosis occurs in domesticated and wild animals and birds in most parts of the world, although surveys indicate differences in area prevalence. The studies in farm animals have been summarized in the literature.2,4

A national survey in swine in the United States found a seroprevalence of
20%. The rate of seropositivity was higher in breeding swine than in feeders, and there were geographical differences with the percentage of positive farms varying from 22% to 89% in different States. On a worldwide basis, the seropositive prevalence in swine is 22% with a range of 0–97%. Equivalent figures for other species are: sheep, 21%; goats, 25%; horses, 15%. The true seroprevalence of toxoplasmosis in cattle is not known due to the inaccuracy of the standard serological tests for cattle. The true seroprevalence in cattle is believed to be low, reflective of the relative unimportance of toxoplasmosis in cattle.

While seroprevalence studies indicate relatively high rates of infection in farm animals, the infection is subclinical and T. gondii has virtually no importance as a cause of clinical disease in farm animals with the exception of that associated with abortion and neonatal disease in sheep. A major importance of toxoplasmosis in farm animals is its zoonotic potential.

Source of infection

Cat feces

The source of infection for sheep, cattle and horses is the oocyst passed in the feces of the cat family. In almost all agricultural areas the feces originate from the domestic cat or feral cats.

Cats become infected, and shed oocysts in their feces, as a result of ingesting tissues of intermediate hosts infected with the parasite. Commonly, these are rodents and small birds, but all animals can be intermediate hosts for T. gondii. Rodents pass the organism from generation to generation through congenital infection and thus can provide a reservoir of infection in an area for a long time with the potential for infection of cats and the triggering of massive oocyst contamination of the environment.

The prevalence of infection is highest in young cats hunting for the first time. Following infection of the cat, the period of excretion of oocysts is short, approximately 2 weeks, but it is intense and several million oocysts are excreted in the feces. In a given environment the number of cats excreting oocysts in their feces at any point in time is likely to be quite small, but the contamination of the environment over time is significant.

Domestic and barn cats in farm environments tend to nest and to defecate in hay and straw mows, grain stores, or other loose piles of commodity feeds, thus providing the potential for direct infection of livestock feeds with T. gondii. Fields fertilized with manure and bedding from buildings that contain cats can also be a source of infection.

Feral cats bury feces superficially in the soil, but the action of earthworms and other soil inhabitants can bring infection to the surface to contaminate pastures. Feral cat families can have territories of up to 250 acres and are capable of widely distributing the infective stage of the parasite. Oocysts can be found in feed, water, and soil in the vicinity of livestock units.

Other sources

Oocysts are also the major source of infection for swine, although it is possible for swine to be infected by the ingestion of tachyzoites or bradyzoites present in meat (dead rodents, cannibalized piglets, etc.) or through the ingestion of blood while tail- or ear-biting. Toxoplasma infection has been shown in all wildlife mammalian species tested in the environment of swine units. Direct sheep-to-sheep transmission by close contact with grossly infected placenta and transmission via the semen of infected rams could occur but are not believed to be of significance. However, a recent study in sheep has shown T. gondii to be present in the placental tissue of a high percentage of successful pregnancies and congenital infection may be an important method of maintenance of infection in sheep flocks in the absence of cats.

Risk factors

Pathogen risk factors

Oocysts are extremely resistant to external influences and can survive in the environment for at least 1 year. They can overwinter in cold climates, but are less viable in arid environments. Fifty grams of infected cat feces can contain as many as 10 million oocysts and infection in farm animals can be established by the ingestion of fewer than 40 oocysts. Oocysts are destroyed by exposure to temperatures between 90°C (194°F) for 30 seconds and 50°C (122°F) for 2.5 minutes.

Environmental and management risk factors

In sheep, a high rate of infection has been shown to be related to a high rainfall, which allows longer survival of oocysts on pasture. The prevalence of infection in small ruminants is much lower in hot, dry arid countries than in those with wet climates.

Sheep raised in cat-free areas have almost no toxoplasmosis, whereas sheep raised in similar environments with cats can have an infection rate as high as 32%. In many recorded outbreaks with high prevalence rates in sheep and goats there has been serious exposure to stored feed containing cat feces. Cat access to sow's is also a risk factor for disease in swine.

Other management risk factors include housing. Swine housed outdoors are at significantly greater risk for infection in some areas, and prevalence is lower in sow's that are kept totally confined. Pig meat is a significant source of infection in humans and the trend to 'animal friendly' outdoor rearing may increase the risk to humans.

Seroconversion may occur more frequently in sheep during the summer pasturing period than during winter housing.

Experimental reproduction

Sheep

Experimental disease can be achieved by challenge with oocysts, tissue cysts and tachyzoites. The ewe may show a febrile response during the parasitic phase 5–12 days following infection. Abortion and fetal mortality occur in sheep that suffer a primary infection during pregnancy. The organism invades the placenta and can be detected in the fetus between 5 and 10 days after the onset of the parasitism. Infection may result in resorption, abortion or the birth of stillborn or congenitally infected live lambs. Infection in early pregnancy (less than 60 days) before the fetus acquires immunological competence usually results in embryonic death and resorption and a barren ewe. Infection in mid-pregnancy generally results in abortions and the birth of stillborn lambs whereas ewes infected in late pregnancy (greater than 110 days) may give birth to live but congenitally infected lambs.

Cattle

Cattle are relatively resistant to infection. Diarrhea, anorexia, poor weight gain, depression, weakness, fever, and dyspnea follow challenge of calves with pathogenic strains. With strains of low virulence there is a mild fever and lymphadenopathy, and the organisms are detectable only in the lymph nodes and for only a few weeks. Adult cows are also relatively insensitive and it is apparent that cattle do not readily acquire persistent T. gondii infections, probably because of rapid elimination of parasites from the tissues.

Many historical reports of outbreaks of toxoplasmosis in cattle were probably sarcocystosis, as serological tests employed in most studies lacked sufficient specificity for diagnosis of toxoplasmosis. T. gondii is not important in causing abortion or clinical disease in cattle, but is recorded. Other ruminants

Large doses of oocysts fed to goats cause a febrile, anorectic, fatal illness, and pregnant does abort. The pathogenesis of the abortion is as for sheep. The reaction
in buffalo calves is described as paracute, with pulmonary consolidation, necrotic foci in all organs, and fluid accumulations in body cavities.

**Pigs**

Infection is relatively easily established in pigs, but is generally not associated with clinical disease or only with a short period of fever and growth suppression. There is a greater susceptibility to infection in young pigs, with piglets below the age of 12 weeks much more susceptible than older animals. With a mild strain and pigs of 8–10 days of age, the reaction is minor, but day-old pigs may have a high mortality rate. Infections induced by tissue cysts are generally less severe than those induced by the ingestion of oocysts and consist of inflammatory and degenerative changes in numerous organs as with other animal species. Congenital toxoplasmosis is not easily reproduced experimentally despite its association with syndromes of neonatal mortality in the field.

**Horses**

These appear to be relatively non-susceptible to the development of the disease or the persistence of infection, and attempts at experimental transmission are rarely successful.

**Economic importance**

Abortion and neonatal mortality in sheep and goats are the most common clinical manifestations of infection with *T. gondii*. Infection is relatively easily established in pregnant sheep and goats; veterinarians and farm workers, especially if pregnant or immunocompromised, should take precautions to avoid infection when handling infected material.

Toxoplasmosis poses an occupational risk for veterinarians, farmers, and slaughterhouse workers who handle infected material. The risk is particularly high with contact with lambing ewes in infected flocks; veterinarians and farm workers, especially if pregnant or immunocompromised, should take precautions to avoid infection when handling infected material.

**PATHOGENESIS**

*T. gondii* is an intracellular parasite that attacks most organs, with predilection for the reticuloendothelial and central nervous systems. Sporozoites from oocysts, or bradyzoites from tissue cysts, invade and penetrate cells by an active process and multiply in the intestinal epithelium. After invasion of a cell, the parasite multiplies and eventually fills and destroys the cells. Liberated toxoplasma reach other organs via the bloodstream after release from their development site. The stage of parasitemia commences approximately 5 days after initial infection and declines with the development of immunity 2–3 weeks after infection, at which stage the organism localizes in tissue cysts.

The clinical character of the disease varies with the organs attacked, which itself varies depending on whether the disease is congenital or acquired. The principal manifestations are encephalitis when infection is congenital, and febrile exanthema with pneumonitis and enterocolitis when very heavy infections occur postnatally. However, the vast majority of infections occur without any clinical signs, and tissue cysts can be found in many animals and appear to cause no harm. When the immunity of the animal falls because of stress, disease or immunosuppressive therapy, tissue cyst rupture and large numbers of inflammatory cells invade surrounding tissue. The characteristic granulomatous lesions are thought to be the result of a hypersensitivity reaction.

**Pregnant sheep and goats**

Abortion and fetal mortality occur in sheep that suffer a primary infection during pregnancy. In the ewe, the infection is limited by the developing immune response; however, this does not limit the infection in the placenta. The fetus and the ability of the fetus and its associated placenta to respond with a protective response depends upon the age of the fetus at the time of infection.

**Immunocompetence to *T. gondii***

Immunocompetence to *T. gondii* is not present before 60 days of gestation and infection in early or mid-pregnancy results in fetal death, with resorption or mummification. Some lambs infected in mid-pregnancy may survive to near term and be stillborn, or may survive to parturition but are weak and die shortly following birth. Parasite multiplication in the placenta results in multiple foci of necrosis, and placental abnormality may contribute to abortions and to the birth of weak lambs. Also, congenital brain infection may result in locomotory and sucking dysfunction. Only those sheep that become infected during pregnancy abort. With infection in late pregnancy, the fetus can mount an immune response and is usually born live, infected, and immune. Infection of pregnant and non-pregnant sheep provokes sufficient immunity to prevent abortion in future pregnancies.

**CLINICAL FINDINGS**

The clinical syndrome and the course of toxoplasmosis vary a great deal between species and between age groups. The only clinical syndrome recognized with any regularity in the field is abortion and neonatal mortality in sheep. The other, less common, syndromes are as follows.

**Cattle**

In cattle, the disease usually runs an acute course - fever, dyspnea, and nervous signs, including ataxia and hyperexcitability, in the early stages, followed by extreme lethargy. Stillborn or weak calves that die soon after birth may also be observed. Toxoplasmosis plays no significant role
in bovine abortion. Congenitally affected calves show fever, dyspnea, coughing, sneezing, nasal discharge, clonic convulsions, grinding of the teeth, and tremor of the head and neck. Death occurs after a course of 2–6 days.

Pigs

Pigs are highly susceptible, and in outbreaks pigs of all ages can be affected. In adult pigs there is debility, weakness, incoordination, cough, tremor, and diarrhea, but no fever. Young pigs are often acutely ill with a high fever of 40–42°C (104–107°F), they develop diarrhoea, and die after a course of several weeks. Pigs of 2–4 weeks of age have additional signs, including wasting, dyspnea, coughing, nervous signs, especially ataxia. Pregnant sows commonly abort, piglets are premature or stillborn, or survive and develop the above syndrome at 1–3 weeks of age. Toxoplasmosis may be the cause of a resident problem of abortions and stillbirths in a pig herd.

Sheep

In sheep, although a syndrome of fever, dyspnea, generalized tremor, abortions, and stillbirths can occur, the clinical manifestation of the systemic disease in the ewe is rare. The principal manifestations of toxoplasmosis in sheep are fetal resorption, abortion, the birth of mummified or stillborn lambs, neonatal death, and the birth of full-term lambs that show locomotor and sucking disorders.

Abortion commonly occurs during the last 4 weeks of pregnancy and the rate may be as high as 50%. Full-term lambs from infected ewes may be born dead, or alive but weak, with death occurring within 3–4 days of birth. Lambs affected after birth show fever and dyspnea, but a fatal outcome is uncommon. Fetal resorption can occur in ewes infected in early pregnancy.

Goats

In goats, caprine toxoplasmosis is manifested by perinatal deaths, including abortions and stillbirths. Systemic disease, with a high case fatality rate, can occur, especially in young goats.

Horses

Clinical disease is rare in horses.

CLINICAL PATHOLOGY

Serological tests available for the detection of humoral antibodies to \( T. gondii \) include the Sabin–Feldman dye test, the indirect hemagglutination assay, the direct fluorescent antibody test (IFAT), the modified agglutination test (MAT), the latex agglutination test (LAT), the enzyme-linked immunosorbent assay (ELISA), and the immunosorbent agglutination assay test (IAAT). Serological tests are commonly used to determine the presence of toxoplasmosis, but the sensitivity and specificity vary with the test and with the same test between species. Tests in cattle pose a particular problem. In cattle and swine, agglutination tests that use whole \( T. gondii \) tachyzoites are suitable, but the latex agglutination tests that use soluble antigens, and the Sabin–Feldman dye test lack sensitivity and specificity.

Sheep abortion

Serological testing to establish toxoplasmosis as the cause of abortion is of limited value. A negative titer will rule out toxoplasmosis but, since antibody persists for years, a positive titer will only indicate that the animal has been exposed to infection at some stage of her life. Seroprevalence rates are normally high in sheep and swine. Rising titers in paired samples are more informative, but may be of limited value in the diagnosis of abortion in sheep where infection and antibody response may precede the abortion storm. In sheep, it is more informative to test pleural or peritoneal fluid of aborted fetuses for the presence of antibody. An IgG avidity ELISA using a dominant membrane protein (P30) of \( T. gondii \) is claimed to be able to differentiate between acute and chronic infections in sheep. Polymerase chain reaction assay (PCR) can be used to detect \( T. gondii \) in infected fetal tissues.

Infection in pigs

MAT, IFAT and a commercially available ELISA test have been shown to have equivalent sensitivity and specificity in swine and can be used for serological and epidemiological studies in this species. Meat juice taken from heart or tongue from pig carcasses after slaughter can be tested for antibody and a PCR for detection of the infection in meat is described.

NECROPSY FINDINGS

Multiple, proliferative, and necrotic granulomata are characteristic of toxoplasmosis, and in cattle the lesions may undergo calcification. The lesions occur most commonly in the nervous system, myocardium, and lungs. When there is visceral involvement, pneumonia, hydrothorax, ascites, lymphadenitis, intestinal ulceration, and necrotic foci in the liver, spleen, and kidneys may be observed.

Abortion

In sheep, there may be involvement of the uterine wall, the placenta, and the fetus. The lesions in the fetal lambs are usually limited to focal necrotic lesions in brain, liver, kidney, and lungs; pathological lesions are much more common and severe in the placenta. The characteristic lesions are confined to the cotyledons and consist of foci of inflamation and necrosis, which may produce macroscopically visible white foci. On histological examination, granulomatosus, necrotic lesions can be found in the viscera and in the brain. Toxoplasma can be found in the cells of most organs, particularly the lungs and brain. The organism is not easily demonstrated in aborted sheep fetuses or in their placentas.

In swine, the prominent lesions are necrotic placentitis, non-suppurative encephalomyelitis, and myocardial degeneration. In contrast to sheep, grossly visible areas of necrosis are not present in the placenta, but numerous organisms may be visible on microscopic examination of the placenta. Experimentally, there is also myocardial degeneration, necrosis, and mineralization. It is probable that many cases previously diagnosed as bovine toxoplasmosis were actually cases of neosporosis or sarcosporidiosis.

Immunohistochemical staining can be used to identify the parasite in formalin-fixed material. Serological testing of fetal thoracic fluid can be useful in those fetuses that are immunocompetent at the time of abortion. A PCR can be used for the detection of antigen in ovine tissue and can be used on autolysed tissue.

On rare occasions, bioassay must be performed to confirm the identity of the parasite and is the most sensitive method of detecting infection. Aseptically collected brain, lung, and diaphragm is administered orally, or by intracebral or intrapentroneal injection, to mice, or orally to cats. A positive diagnosis depends upon the presence of toxoplasma cysts in the brains of the mice 8 weeks after the injection or the secretion of oocysts by the cat. Cats are a more sensitive assay because of the volume of tissue that can be tested.

Samples for confirmation of diagnosis

- Parasitology – fresh or chilled brain, lung, placenta (BIOASSAY) (rarely required)
- Serology – fetal thoracic fluid (IHA)
- Histology – placental cotyledons, lung, liver, brain, spinal cord, kidney, heart (LM, IHC).

DIFFERENTIAL DIAGNOSIS

Toxoplasmosis is rarely considered in a primary diagnostic list other than with problems of abortion and associated neonatal mortality. The differential diagnosis of abortion in cattle is dealt with under brucellosis, in sheep under brucellosis, and in pigs under leptospirosis. The causes of encephalitis in animals are listed under that heading, and of pneumonitis under pneumonia.
TREATMENT

Treatment with a combination of sulfamethazine and pyrimethamine has proved effective in mitigating the effects of experimentally induced toxoplasmosis in pregnant ewes, it should be considered for therapy in the face of an outbreak of toxoplasmosis abortion. Treatment was administered over 3 days for three periods with an interval of 5 days between the start of each treatment period. These drugs are effective against the proliferating parasites in the acute stage of the disease, but will usually not eradicate infection and have limited activity on the organisms in tissue cysts.

CONTROL

There are two concerns in the control of toxoplasmosis in agricultural animals. The first is the concern to reduce the economic effects of infection in agricultural animals, and the second is to reduce the risk for human disease associated with consumption of infected meat.

Farms

Cat control

The elimination of cats in the farm environment will preclude feed contamination and contamination of pasture areas. While it is possible to ban domestic cats from the farm, this will not, in general, totally eliminate the risk for toxoplasmosis due to the range of activities of cats from adjacent areas, the presence of feral cats and the occurrence of wind-borne spread of oocysts. Nevertheless, risk for infection will be reduced by eliminating cats from the farm environment or restricting them to neutered animals. Where possible, feeds should be stored in cat-proof areas. In swine units, control of rodents and of access of pigs to any carrion is an important control measure. On all farms, the carcasses of infected or suspect animals should be totally destroyed, or at least be made inaccessible to carnivores.

Serological testing

With sows housed both indoors and outside, serological testing to determine seroprevalence and seroconversion associated with the two housing areas may determine if housing management needs change. Serological testing can also be used to determine housing/pasture areas of risk for sheep, risk for abortion in sheep, and whether anti-toxoplasmal drugs or vaccination should be used for protection.

There is an effective and long-lasting immunity following primary toxoplasma infection and ewes that have aborted should be kept in the flock. Exposure of ewes to natural infection in a contaminated environment prior to breeding would be an effective method of preventing reproductive disease, but is difficult to achieve with certainty.

Prophylaxis

Feeding monensin at a dose of 15 mg/head per day during the first 100 days of pregnancy has been shown to reduce lamb loss following experimental infection, as has decoquinate fed at 2 mg/kg daily. Decoquinate is more palatable and has less risk of toxicity, and medication offers an option for control in ewes that are seronegative for T. gondii antibodies and likely to be exposed in pregnancy to feed, water or an environment contaminated with toxoplasma oocysts. Both drugs are best fed to ewes before they encounter infection and are not effective as therapeutic agents.

Vaccination

Tachyzoites from an incomplete strain, S48, of T. gondii are used in a vaccine for sheep which is available commercially in some countries. S48 tachyzoites readily infect seronegative sheep, but do not initiate chronic infection or tissue cysts and the parasite cannot be demonstrated in muscle or brain 6 weeks after vaccination. Ewes should be vaccinated at least 3 weeks before mating, and a single injection will protect the life of the sheep. In flocks where toxoplasmosis is a cause of lamb loss, initial vaccination of the whole flock followed by vaccination of replacement ewes is a better economic option than that of just vaccinating replacement ewes. Vaccination does not entirely protect the pregnant ewe against parasitism or the infection of the fetus following challenge with virulent T. gondii oocysts, but there is a significant reduction in the birth rates of non-viable lambs. It has been postulated that vaccination results in reduced numbers of tachyzoites invading the gravid uterus or fetus, with a consequent reduced potential for inducing significant pathology in the placenta and the fetus. The immunity appears to be cell-mediated. Experiments with an adjuvenated vaccine in pigs show protection from clinical challenge and a reduction in recoverable toxoplasma from tissues of vaccinated challenged pigs.

Reduction of zoonotic risk from meat

Oocysts from cat feces are a major cause of infection in man, but the ingestion of cysts in meat from sheep, swine and, to a lesser extent, cattle is also a major cause of human infection. The implementation of control procedures on the farm will reduce that risk and the major influence will be by the reduction or elimination of cats on the farm. The infectivity of meat can be destroyed by irradiation and proper cooking. Discussions of other strategies for control of food-borne toxoplasmosis are available.

REVIEW LITERATURE

REPORTS OF THE SCIENTIFIC PROGRAM; SECTION ON TOXOPLASMOsis

Equine protozoal myeloencephalitis

The cause is Sarcocystis neurona, an amniciplexan protozoan.1-3 Isolates of S. neurona can vary in their antigenic composition, such that variable responses are observed on immunoblot tests, but the importance of this variation in terms of pathogenicity of the organism is unknown. Neospora spp., including N. hughesi, cause myeloencephalitis rarely in horses.5,6

ETIOLOGY

The disease is infectious but not contagious. The definitive host is the opossum (Didelphis spp.). Other species of opossums and marsupials that have not been experimentally infected but that act as transport hosts include marsupial marsupials. Sporocysts ingested by these hosts encyst in muscle where they remain infective in the environment for months, drying, high humidity, or freezing and thawing.29 Birds and insects also serve as transport hosts. Sporocysts ingested by the intermediate host undergo schizogyony and ultimately form infective sarcocysts in muscle. Recently, S. neurona sarcocysts were detected in muscle of a 4-month-old filly, suggesting that horses might serve as intermediate hosts of the organism.30 This finding needs to be confirmed as the conventional wisdom is that in horses, S. neurona does not complete schizogyony and remains as uninfected merozoites in neural tissue.3,2 S. neurona sarcocysts do not occur in the muscle of horses and are therefore not infective to other animals.

There is no evidence of transplacental infection of foals.32

The definitive and intermediate hosts of N. hughesi have not been determined. Dogs are the definitive host of the closely related N. caninum.

PATHOGENESIS

Details of the pathogenesis of EPM are unknown. It is assumed that after infection, probably by ingestion, sporocysts excyst and release merozoites which penetrate the gastrointestinal tract and enter endothelial cells. Subsequently, merozoa (schizonts) develop which on maturation rupture and release merozoites. Schizonts are present in cells of the central nervous system, including neurons, glial cells, and intrathelial macrophages. Schizonts multiply in the infected cells, as evidenced by the presence of merozoites. Infection induces a non-suppurative inflammation, characterized by accumulations of lymphocytes, neutrophils, eosinophils, and gitter cells. Infection of neurons, and the associated inflammatory reaction, disrupt normal nervous function and contribute to the clinical signs of weakness, muscle atrophy, and deficits in proprioception.

Clinical signs

Variable, but commonly asymmetric spinal ataxia, focal, neunogenetic muscle atrophy, and/or cranial nerve dysfunction.

Clinical pathology

No characteristic changes in blood or cerebrospinal fluid. Western blot of blood or CSF has high sensitivity but low specificity.

Diagnostic confirmation

Histologic demonstration of S. neurona in nervous tissue.

Lesions

Non-suppurative myeloencephalitis with schizonts and merozoites in neurons, glial cells, and leukocytes.

Treatment

Antiprotozoal agents, including ponazurial, nitazoxanide, or a combination of a sulfonamide and pyrimethamine.

Control

Prevent exposure to S. neurona by minimizing fecal contamination by opossums of feed. A vaccine is available by minimizing exposure to S. neurona by minimizing fecal contamination by opossums of feed. A vaccine is available but not recommended.

Risk factors

Risk factors for development of EPM include season of the year, with the highest incidence of new cases being in summer and fall,27 age; use; protection of feed; and presence of opossums on the farm.36 The disease occurs in horses from 2 months to 19 years of age.37 Horses younger than 1 year of age are at lower risk of developing disease than horses 1-4 years of age.37 Older horses are less likely to develop the disease.37 Protection of feed from contamination by opossum feces is associated with a decreased risk of disease, whereas presence of opossums on the premises is associated with an increased risk of disease.38 Horses used primarily for racing and showing are at increased risk of developing EPM with an annual incidence of 38 new cases per 10,000 horses for horses used for racing compared to an incidence of 6 cases per 10,000 horses for horses used for pleasure or farm work.11 Horses used for showing or competition have the highest annual incidence of 51 cases per 10,000 horses per year.11 The presence of previous illness is a risk factor for development of EPM.19 Transportation for more than 55 hours increases the susceptibility to EPM of horses experimentally infected with S. neurona.21

Transmission

S. neurona is believed to have the two-host life cycle (predator-prey) typical of other Sarcocystis and Toxoplasma spp. The definitive host is the opossum, Didelphis virginiana, and intermediate hosts include raccoons, cats, skunks, sea otter, and armadillo. The domestic cat, 9-banded armadillo, racoon, and skunk can be infected by ingestion of sporocysts and develop sarcocysts in muscle which when fed to opossums induce shedding of sporocysts22-26 thereby confirming the potential for these species to serve as intermediate hosts. Cats living on farms at which EPM has been diagnosed in horses have a higher rate of seroprevalence (40%) than do cats living in a city (10%),27 providing evidence for a role of cats in the epidemiology of the disease. However, others have detected a lower prevalence of seropositivity (5%) to S. neurona among cats in Texas and conclude that cats are not likely to play an important role in the epidemiology of EPM.28 At least in those areas where raccoons are present they are probably the most important intermediate host.

The definitive host is infected by ingestion of sarcocysts of S. neurona encysted in muscle of the intermediate host. The intermediate host is infected by ingestion of sporocysts derived from rupture oocysts passed in the feces of the definitive host. Sporocysts can remain infective in the environment for months, but are probably, based on behavior of other Sarcocystis spp. oocysts, killed by drying, high humidity, or freezing and thawing.29 Birds and insects also serve as transport hosts. Sporocysts ingested by the intermediate host undergo schizogyony and ultimately form infective sarcocysts in muscle. Recently, S. neurona sarcocysts were detected in muscle of a 4-month-old filly, suggesting that horses might serve as intermediate hosts of the organism.30 This finding needs to be confirmed as the conventional wisdom is that in horses, S. neurona does not complete schizogyony and remains as uninfected merozoites in neural tissue.3,2 S. neurona sarcocysts do not occur in the muscle of horses and are therefore not infective to other animals.

There is no evidence of transplacental infection of foals.32

The definitive and intermediate hosts of N. hughesi have not been determined. Dogs are the definitive host of the closely related N. caninum.

The disease occurs in horses and ponies in Canada, United States, Central America, and Brazil. Reports of neurological disease in horses with antibodies to S. neurona in France have yet to be confirmed, but might represent cases of EPM in native horses outside of the Americas.5 The disease is reported in other countries in only horses imported from the Americas.6 Distribution of the disease appears to correlate with the range of the definitive host, Didelphis virginiana in North America, or the related species D. marsupialis and D. albiventris in South America. The disease has not been reported in donkeys and mules. Neurological disease associated with S. neurona has been reported in armadillos, sea otters, harbor seals, skunks, raccoons, zebras, lynxes, and cats.5,6

The disease usually occurs sporadically in endemic areas, although epidemics on individual farms are reported.10 The incidence of EPM is estimated to be 14 new cases per 10,000 horses per year.11 The case fatality rate is approximately 7%, although up to 14% of horses are sold or given away because they are affected by EPM.11 Approximately 40% of horses recover completely and another 37% improve but do not recover from the disease.13 Another study reports that only 55% of horses with EPM examined at a referral hospital were alive a minimum of 3 years after diagnosis and treatment.12 Seroepidemiological studies, based on detection by Western immunoblot test of multiple antibodies to S. neurona in serum,23 indicates that 45-60% of horses in the United States are exposed to the agent but do not develop disease.14-17

Vaccination with a product containing killed S. neurona induces a detectable antibody response in both serum and, in approximately 50% of horses, in the cerebrospinal fluid.18

Risk factors

Risk factors for development of EPM include season of the year, with the highest incidence of new cases being in summer and fall,27 age; use; protection of feed; and presence of opossums on the farm.36 The disease occurs in horses from 2 months to 19 years of age.37 Horses younger than 1 year of age are at lower risk of developing disease than horses 1-4 years of age.37 Older horses are less likely to develop the disease.37 Protection of feed from contamination by opossum feces is associated with a decreased risk of disease, whereas presence of opossums on the premises is associated with an increased risk of disease.38 Horses used primarily for racing and showing are at increased risk of developing EPM with an annual incidence of 38 new cases per 10,000 horses for horses used for racing compared to an incidence of 6 cases per 10,000 horses for horses used for pleasure or farm work.11 Horses used for showing or competition have the highest annual incidence of 51 cases per 10,000 horses per year.11 The presence of previous illness is a risk factor for development of EPM.19 Transportation for more than 55 hours increases the susceptibility to EPM of horses experimentally infected with S. neurona.21

Transmission

There is no evidence of transplacental infection of foals.32

The definitive and intermediate hosts of N. hughesi have not been determined. Dogs are the definitive host of the closely related N. caninum.
Mechanisms permitting infection and proliferation of the organism have not been well defined. Horses with EPM have lesser cell-mediated immunity than do asymptomatic horses, and the decrease in cell-mediated immunity appears to be due to *S. neurona* suppressing immune responses to parasite-derived antigens. However, foals with severe combined immunodeficiency administered *S. neurona* do not develop neurologic disease, despite prolonged parasitemia and infection of visceral organs by the organism, whereas immunocompetent horses do not have prolonged parasitemia but do develop neurologic disease.

**CLINICAL FINDINGS**

The incubation period after experimental infection of young horses ranges between 28 and 42 days, but is not known for the spontaneous disease. The clinical findings of EPM in horses are protean, and in endemic areas EPM should be considered as a diagnosis in any horse with clinical signs referable to the nervous system. *S. neurona* can infect any area of the brain and spinal cord, and may affect more than one site in an individual horse. Clinical signs of EPM range from barely perceptible changes in gait or behavior to recumbency, muscle atrophy, or seizures. The onset of signs may be insidious and gradual, or acute and rapidly progressive. Affected horses do not have increased temperature or heart rate, unless complications of the nervous disease occur.

**Spinal ataxia**, evident as weakness, hypometria or hypermetria, and defects in proprioception are common manifestations of EPM. Multifocal spinal or cervical disease causes all four limbs to be affected, while lesions caudal to the cervical intumescence cause signs in the rear limbs only. Signs of spinal ataxia range from subtle changes in gait which are difficult to differentiate from obscure lameness due to musculoskeletal disease, through obvious spinal ataxia evident as truncal sway, toe dragging, and circumduction of feet, to spontaneous falling and recumbency. **Asymmetry** of clinical signs, in which one limb is affected more than the contralateral limb, is highly suggestive of EPM, as cervical stenotic myelopathy and equine degenerative myelopathy usually cause symmetrical ataxia.

Lesions in the sacral cord cause signs of **cauda equina syndrome**, including tail paresis and urinary and fecal incontinence. Lesions affecting spinal cord gray matter cause focal, **asymmetric muscle atrophy**, absent reflexes, or focal areas of **sweating**. Muscles frequently affected include the quadriceps, biceps femoris, epaxial muscles, and the supraspinatus/infraspinatus group. Equine protozoal myeloneuropathies can present as a brachial plexus injury evident as radial nerve paralysis.

**Cranial nerve disease** is a common manifestation of EPM. Common syndromes include:

- **Vestibular disease** (CN VIII), evident as circling, nystagmus, head tilt, and falling toward the affected side
- **Unilateral facial nerve paralysis** (CN VII), evident as ear droop, lack of palpebral or corneal reflex and menace on the affected side, and displacement of the upper lip and nares away from the side of the lesion
- **Dysphagia** (CN IX, X, XII) and persistent dorsal displacement of the soft palate
- **Tongue paralysis** (CN XII)
- **Masseter atrophy** and weakness (CNV)
- **Hypalgesia** (Lack of sensation) of the nostrils and skin of the face (CNV).

EPM may also manifest as changes in personality and behavior, headshaking, and seizures.

**CLINICAL PATHOLOGY**

There are no characteristic changes in the hemogram or serum biochemical variables. **Diagnosis** has focused on the demonstration of antibodies to *S. neurona* in serum or CSF by western blot, indirect fluorescence testing, or IgM capture ELISA. Interpretation of the results of western blot analysis of serum or CSF, for IgG antibodies to *S. neurona* is problematic because of the potential for blood contamination of the sample during collection, and the high sensitivity but low specificity of the test.

Blood contamination of the sample is problematic in horses that are seropositive for antibodies to *S. neurona* and in which it is desired to know if antibodies are present in cerebrospinal fluid. Contamination of cerebrospinal fluid with blood can introduce antibodies from serum into the otherwise antibody free cerebrospinal fluid thereby causing a 'false' positive test. Contamination of cerebrospinal fluid with small quantities of blood with high concentrations of antibodies to *S. neurona* might not be detectable using red blood cell counts, albumin quotient, or immunoglobulin index, but could yield a positive result on western blot testing.

The western blot test for detection of antibodies to *S. neurona* is sensitive (87%) but has poor specificity (44–60%). The utility of the test therefore depends on the pretest probability that the horse has EPM. The high sensitivity of the test means that the **positive predictive value** of a positive test in a horse with unequivocal signs of neurologic disease consistent with EPM, and from an area in which the disease is endemic, is very good. However, the positive predictive value of a positive test is very poor in horses with vague, or no, signs of nervous disease, or in horses from areas in which the disease is not endemic. The **negative predictive value** is good in either instance in that horses that test negative for the presence of antibodies are unlikely to have EPM.

A negative result on a western blot analysis of serum or CSF, therefore, virtually eliminates the disease from the potential diagnoses, whereas a positive test in a horse with a high pretest probability of the disease contributes little to confirming the diagnosis. A positive test in a horse with a low probability of having the disease, such as presale testing of a clinically normal horse, does not mean the horse has the disease and is virtually useless in any assessment of the horse.

Foals of seropositive mares acquire antibodies, but not infection, by ingestion of colostrum from the dam. These antibodies can be detected in both serum and cerebrospinal fluid of foals. The mean time for foals to become seronegative for antibodies to *S. neurona* is 4.2 months. Detection of antibodies to *S. neurona* in serum or cerebrospinal fluid of foals less than 4–6 months of age, even those with neurologic disease, should be interpreted with caution as the antibodies are likely derived from the dam.

An **indirect fluorescent antibody** test reliably detects antibodies to *S. neurona* in serum and cerebrospinal fluid of infected horses. This test has the advantages of providing quantitative results, cheaper to perform, and is more accurate than immunoblots in the detection of antibodies. An IgM capture ELISA detects the presence of IgM antibodies to a 56 kDa *S. neurona*-specific antigen in serum and cerebrospinal fluid of naturally and experimentally infected horses, thereby providing evidence of recent infection. Demonstration of recent infection in a horse with signs of neurologic disease increases the probability that the horse has EPM.

Examination of other variables in CSF is of limited use in the diagnosis of EPM, and measurement of creatine kinase activity in CSF has no diagnostic usefulness. The use of the **albumin quotient** or **IgG index** to detect blood contamination of cerebrospinal fluid, or the intrathecal production of IgG is unreliable and not useful in the diagnosis of EPM.

**NECROPSY**

Lesions are limited to the spinal cord and brain, with the exception of neurogenic muscle atrophy. Gross lesions of hemorrhage and malacia may be visible in the central nervous system tissue. The lesions are asymmetrical, but may be more frequently encountered in the cervical and
The initial dosage is 5 mg/kg q 24 h which is continued for 28 days if signs of improvement are evident after 14 days. If signs of improvement are not seen after 14 days, the dosage is increased to 10 mg/kg orally q 24 for 14 days. Few adverse effects are noted, even at 30 mg/kg orally once daily for 28 days.48

Nitazoxanide is administered at 25 mg/kg bodyweight orally for the first 5 days of treatment and then at 50 mg/kg orally for days 6–28 of treatment. Adverse effects noted include fever, anorexia, diarrhea, and worsening of clinical signs of neurologic disease.49 Nitazoxanide is apparently effective in the treatment of EPM, based on a study of seven horses with the disease, but there are no reports of treatment of large numbers of horses.50

Administration of the combination of sulfadiazine (or similar drug, 20 mg/kg, PO) and pyrimethamine (1–2 mg/kg, PO) every 24 hours given 1 hour before feeding is effective in approximately 60–70% of cases.5 The treatment is continued for at least 90 days if complete resolution of clinical abnormalities occurs, or longer if the signs of EPM do not resolve. Side-effects of the administration of a combination of sulfonamide and pyrimethamine include enterocolitis, anemia, and abortion.50 Polic acid is often added to the diet of horses being treated for EPM, but this cannot be recommended because of its lack of efficacy in preventing anemia in horses.50,51 and its ability to cause severe congenital abnormalities in foals.52

Orally administered synthetic folates interfere with normal folate metabolism in horses being administered anti-folate drugs resulting, paradoxically, in folate deficiency.51 Adequate intake of folates in antiprotozoal-treated horses can be assured by feeding a diet containing good quality green foliage. The decision to stop treatment in horses that do not completely recover is difficult. Some authorities recommend resampling CSF and continuing treatment until antibodies to S. neurona are no longer detectable. However, given that normal horses often have antibodies in their CSF, and that some treated horses never lose their positive western blot test, the decision to stop treatment should not be based entirely on this variable.

Some horses have a transient worsening of clinical signs in the first week of treatment. This is presumed to be due to the effect of the antiprotozoal agent causing death of protozoa with subsequent inflammation and further impairment of neurologic function. Relapse of the disease occurs in some horses when treatment of antiprotozoal medication is stopped.

Supportive treatment of affected horses includes anti-inflammatory drugs (flunixin meglumine, 1 mg/kg IV, every 8–12 h; dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline IV, every 24 h for 3 days) and nutritional support for horses that cannot eat. Flunixin meglumine is often administered twice daily for the first 3–5 days of treatment with ponazuril or nitazoxanide, purportedly to reduce the inflammatory effects of death of protozoa in the central nervous system.

CONTROL

A vaccine composed of killed S. neurona is available in the United States. However, the efficacy of this vaccine has not been demonstrated. Furthermore, because the vaccine induces detectable antibody in serum and cerebrospinal fluid of vaccinated horses, there is concern that it can impair the diagnosis of EPM.18 Given the lack of demonstrated efficacy and potential for interference with diagnosis of EPM, use of the vaccine currently available in the United States (2005) is not recommended.

Sporocysts of S. neurona are resistant to usual concentrations of many of the conventional disinfectants including sodium hypochlorite (bleach), 2% chlorhexidine, 1% betadine, 5% benzylic chlorphenol, 13% phenol, 6% benzylic ammonium chloride, and 10% formalin.53 The organism is killed by heating to 55°C for 15 min or 60°C for one minute.53

Because protection of feed from contamination by opossums has been demonstrated to reduce the risk of horses developing EPM54 it is prudent to employ measures to reduce the exposure of animals and feed to opossum feces, and possibly feed of birds that might act as transport hosts.

There is interest in pharmacologic means of preventing infection of horses by S. neurona. Pyrantel pamoate has some efficacy against S. neurona in vitro but daily administration (2.6 mg/kg body weight in feed) does not prevent S. neurona infection of horses.54

REVIEW LITERATURE

Theileriases are tick-borne protozoan diseases associated with Theileria spp. in cattle, sheep, and goats as well as in wild and captive ungulates. The genus Theileria belongs to the Apicomplexa group which includes Babesia, Toxoplasma, Neospora, Plasmodium, among others. The life cycle of Theileria spp. involves cyclical development in ticks to form sporozoites which, on being injected with tick saliva into the mammalian host, develop into schizonts in leukocytes and then piroplasms (merozoites) in erythrocytes. The diseases in ruminants are characterized by fever and lymphoproliferative disorders and are associated with varying degrees of leukopenia and/or anemia.

**Theileria spp.** are found throughout the world and their nomenclature and classification, though still controversial, are being gradually elucidated through molecular characterization. The important pathogens of cattle are restricted to certain geographical regions after which the diseases are named1-3 (Table 26.6). **East coast fever** (ECF) associated with *T. parva* and tropical theileriosis (or Mediterranean coast fever) associated with *T. annulata* are the most important and are dealt with separately below. Japanese bovine theileriosis associated with *T. serrata* is probably next in importance.

*T. orientalis* is responsible for **oriental theileriosis**, a milder disease than ECF or bovine tropical theileriosis, and hence also called **benign theileriosis**. It has been proposed that the species found worldwide and responsible for benign theileriosis be named *T. buffeli* (replacing *T. orientalis* in Asia and *T. serrata* in Japan) but genetic differences have been shown between *T. buffeli* and *T. serrata*.4,5 Furthermore, *T. serrata* causes a more severe disease in southeastern Asia, also called Japanese bovine theileriosis. Both *T. buffeli* and *T. serrata* are transmitted by *Haemaphysalis tessulata* ticks. *T.�* is transmitted by *Rhipicephalus serventi*. The important pathogen of sheep and goats is *T. hirii* (synonym *T. restuquardi*), the cause of **malignant ovine theileriosis**.

The disease is enzootic from North Africa through the Middle East to India and China, approximately the same geographical region as bovine tropical theileriosis. Malignant theileriosis in sheep and goats is similar to bovine tropical theileriosis due to *T. annulata*. Like the latter, it is also transmitted by *Hyalomma* spp. but in China, the main vector is *Haemaphysalis* spp. The disease can be chronic, subacute, or acute, depending on the resistance of the sheep or goats, and is seasonal, depending on availability of ticks. The acute disease is characterized by fever and very high mortality in 3–6 days.12,13 Anemia, jaundice, and enlargement of lymph nodes are characteristic, and both piroplasms and schizonts can be demonstrated in smears of blood and tissues, respectively. In subacute and chronic cases, signs are generally less marked except for anemia and emaciation. An indirect fluorescent antibody test is available. Parvaquone and buparvaquone may be used to treat early cases. **Benign ovine theileriosis** is caused either by *T. ovis* or by *T. punctata simia*. Theileriases in cattle are reviewed by *Furr* et al. (1997) and in sheep by *Stanek* et al. (2001).

Africa. Piroplasms are found in blood but there are no overt clinical signs.

In general, the pathogenesis of various forms of theileriosis is dependent on the production of schizonts in lymphocytes and piroplasms in erythrocytes. Thus, T. parva, T. annulata, and T. hirci produce numerous schizonts and piroplasms and are very pathogenic; T. mutans, T. buffeli, and T. ovis rarely produce schizonts but may cause varying degrees of anemia when piroplasms are many in red blood cells, and with T. tauri and T. separata, no schizonts have been described, the parasitemia is usually scanty and the infection is mild or subclinical.

REFERENCES

EAST COAST FEVER (ECF)

**Synopsis**

**Etiology** *Theileria parva*, an apicomplex protozoan parasite of the class Sporozoosida and order Piroplasmida. There has been considerable naming and renaming of *T. parva* and the associated diseases in Africa. ‘Classic’ East Coast Fever (ECF) occurs in East Africa and is associated with *T. parva* transmitted from cattle to cattle by the brown ear tick, *Rhipicephalus appendiculatus*. ECF also occurs either as Corridor disease in eastern and southern Africa or as January disease in central Africa. Corridor disease is transmitted from buffalo to cattle by either *R. appendiculatus* or *R. zambezensis* and the agent responsible used to be called *T. parva lawrencei*. Close contact between buffalo, cattle, and ticks is essential. The disease is more acute than classical ECF, but after serial passage in cattle, it is indistinguishable from classical ECF. January disease occurs mainly between January and March and the agent was named *T. parva bovis*. The disease is also more acute than classical ECF, death sometimes occurring within 4 days. These three clinical diseases are otherwise indistinguishable from one another, hence the causative agents are currently referred to simply as *T. parva*.

**Epidemiology** Endemic disease of cattle in east and central Africa; high mortality and great economic importance.

**Pathogenesis** Tick inoculation of sporozoites → lymphocytes in local lymph node → schizogony → lymphoid proliferation → parasitemia → more lymphoid proliferation → merozoites → erythrocytes → piroplasms → ticks. Damage mainly by schizonts.

**Clinical signs** Fever, enlarged superficial lymph nodes, dyspnea, wasting, and terminal diarrhea.

**Clinical pathology** Schizonts in lymphoblastoid cells, proliferation of lymphoblastoid cells.

**Lesions** Massive pulmonary edema, hydrothorax, hydropericardium, emaciation, hemorhages, lymphadenopathy, and widespread proliferation of lymphoblastoid cells.

**Differential diagnosis list**
- Trypanosomosis/anaelnosis
- Heartwater
- Malignant catarrhal fever/Bovine virus diarrhea/Rinderpest.

**Treatment** Limited success with halofuginone, parvoquone, and tetracyclines.

**Control** Integrated approach involving resistant animal breeds, strategic application of acaricides, and vaccination by injection-and-treatment methods.

**ETIOLOGY**

*Theileria parva* is an apicomplex protozoan parasite of the class Sporozoosida and order Piroplasmida. There has been considerable naming and renaming of *T. parva* and the associated diseases in Africa. ‘Classic’ East Coast Fever (ECF) occurs in East Africa and is associated with *T. parva* transmitted from cattle to cattle by the brown ear tick, *Rhipicephalus appendiculatus*. ECF also occurs either as Corridor disease in eastern and southern Africa or as January disease in central Africa. Corridor disease is transmitted from buffalo to cattle by either *R. appendiculatus* or *R. zambezensis* and the agent responsible used to be called *T. parva lawrencei*. Close contact between buffalo, cattle, and ticks is essential. The disease is more acute than classical ECF, but after serial passage in cattle, it is indistinguishable from classical ECF. January disease occurs mainly between January and March and the agent was named *T. parva bovis*. The disease is also more acute than classical ECF, death sometimes occurring within 4 days. These three clinical diseases are otherwise indistinguishable from one another, hence the causative agents are currently referred to simply as *T. parva*.

**EPIDEMIOLOGY**

**Occurrence**
ECF affects mainly cattle but also buffalo, and occurs in 13 countries in eastern, central, and southern Africa. Its occurrence is related to the distribution of the vector tick which has been recorded from large areas extending from southern Sudan in the north to western Zambia and eastern Zaire in the west, and to Mozambique and Zimbabwe in the south. The disease is prevalent throughout the wetter areas favoring the development of the tick, but is absent from the wet highlands in the horn of Africa. It has been eradicated from southern Africa up to the Zambezi River. The endemic scenarios range from a stable situation with high prevalence of herd infection but low fatality rates (endemic stability), to a low prevalence/high fatality scenario (endemic instability). Endemic stability develops in indigenous zebu cattle exposed to constant tick challenge as in wetter areas whereas endemic instability is seen with commercial production systems utilizing imported breeds or crosses and in areas with a unimodal rainfall pattern that restricts tick activity. Epidemics occur when there is a breakdown in tick control especially during the rainy season or when susceptible animals are introduced into an endemic area.

**Morbidity and case fatality**
All susceptible cattle in endemic areas are at the risk of contracting ECF unless...
they are vaccinated or the tick population is under stringent control. The morbidity and case fatality rates are very high, approaching 90–100% in recently introduced exotic (Bos taurus) breeds and in previously unexposed or naive indigenous cattle. However, indigenous zebu cattle (Bos indicus) and African buffalo in endemic areas have a strong resistance to the disease and calfhood mortality is around 5%.6

Methods of transmission
The vector of ECF is Rhipicephalus appendiculatus and in the field, the disease occurs only where this tick is found, except for Corridor disease which may be transmitted by R. zambeziensis. Other species of Rhipicephalus and Hyalomma spp. can transmit ECF experimentally, but they are not significant. Developmental stages of the parasite occur in the tick and they pass trans-stadially through the stages of larva, nymph and adult, but there is no transovarian transmission. Consequently, larvae or nymphs become infected and transmit infection as nymphs or adults. Adults are more efficient vectors than nymphs. Mechanical transmission is of no significance. The epidemiology of the disease is thus largely dependent on the distribution and habitat of the tick and its ability to complete development to the adult stage, usually during the rainy season. Ticks may live for 1–2 years, but they lose their infection within 11 months.

Risk factors
The most important risk factors relate to the presence of the brown ear tick in a given area and the level of tick burden per animal, even though it takes only one tick to establish an infection that could be fatal. At low infestation rates, an average of five ticks per head (two to three per ear) will sustain endemicity; one to four per head will invite epidemics; while an average of less than one can allow sporadic outbreaks.10 In addition, there is evidence that R. appendiculatus populations that originate from eastern Africa tend to become more highly infected with T. parva than those that originate from southern Africa, and consequently the disease they transmit is more virulent.11

The infection rate in ticks in endemic areas is usually low (1–2%) even though the immunity conferred on recovered or vaccinated animals is no longer thought to be sterile. However, soon after ECF becomes established in susceptible herds, infection rates in ticks become much higher.

Young animals are less susceptible, and indigenous breeds and buffaloes are less clinically affected than exotic breeds, but buffaloes are the carriers of Corridor disease. Other wild Bovidae may help to sustain the population of the tick vector but are not carriers of T. parva. Asiatic or water buffalo is fully susceptible.

Environmental factors
In eastern Africa, R. appendiculatus normally occurs in grass-covered savannah and savannah woodlands, but is usually absent from extensive heavily wooded forest habitats.5 Areas that are too high, too cold, or too dry will not allow the tick to undergo more than one life cycle in a year, thereby reducing the period of transmission of thelerial parasites by the nymphs or adults. For example, the disease is most prevalent in eastern Africa where adult and immature stages of the tick occur simultaneously on cattle, leading to rapid and continuous transmission.11 In southern Africa, by contrast, there is a seasonal life cycle for the tick so that there is little overlap between the activity periods of adults (January to March) and immature stages, thereby reducing the frequency of disease transmission.

Immunological mechanisms
Cattle recovering from ECF have a solid immunity to homologous challenge, but the immunity is not sterile. In endemic areas, premunition is established early and this provides lifelong protection if reinfection continues and the cattle are not moved to a different location where they may be exposed to a different strain of the parasite. Indigenous cattle are able to limit explosive multiplication of schizonts during the acute phase.12 Nutritional or climatic stress may seriously reduce the animal's premunition, even among resistant breeds. While antibody responses to the sporozoite may play some part in protection, immunity is mediated mainly by cellular mechanisms involving cell-mediated cytotoxic T-cell (CTL) responses against surface antigens of macroschizont-infected cells.13 The CTL response is parasite-specific and genetically restricted (major histocompatibility complex or MHC antigens) and the protection can be transferred between immune and naive calves in the CD8+ T-cell fraction emanating from a responding lymph node.7

Experimental reproduction
ECF can easily be reproduced by feeding infected ticks on susceptible cattle or by inoculating cattle with infected tick material, sporozoites or macroschizont-infected tissue culture cells. This is used as a method of immunization. When working with ticks or tick materials, care should be taken to avoid the risk of contracting other tick-borne diseases.

Economic importance
ECF has a major impact on cattle production in eastern, central, and southern Africa. It is estimated that in 1989, ECF killed 1.1 million head of cattle and caused US$168 million in losses.14 Serious losses occur in exotic and indigenous cattle, mainly from reduced production of milk and meat due to morbidity and mortality, as well as from the heavy costs incurred in implementing effective tick control. T. parva does not infect human beings.

Biosecurity concerns
The vector of ECF has strict requirements which limit the spread and establishment of the disease beyond the geographic areas where it normally occurs. It is not contagious.

PATHOGENESIS
Sporozoites of T. parva are injected into the bovine host by the tick in its saliva. Ticks must feed for 2–4 days before sporozoites in their salivary glands will mature and become infective to cattle. One tick can transmit sufficient sporozoites to cause a fatal infection in a susceptible animal. The sporozoites then enter lymphocytes and develop into schizonts in the lymph node draining the area of attachment of the tick, usually the parotid node. Infected lymphocytes are transformed to lymphoblasts which continue to divide synchronously with the schizonts so that each daughter cell is also infected. Eventually, infected lymphoblasts are disseminated throughout the lymphoid system and in nonlymphoid organs where they continue to proliferate. Later, some schizonts differentiate into merozoites, are released from the lymphoblasts and invade erythrocytes where they are referred to as piroplasms and are infective to ticks. Piroplasms ingested by ticks undergo several developmental stages and eventually form sporozoites in salivary glands, thus completing the cycle.

The dominating pathological lesion is generalized lymphoid proliferation resulting from uncontrolled proliferation of T-lymphocytes containing schizonts. This is followed later by necrosis of infected lymphoblasts induced by cytotoxic T-lymphocytes. The severe lymphocytolysis often leads to immunosuppression. Terminally, the animal develops severe pulmonary edema, probably due to release of vasoactive substances from lymphocytes disintegrating in the lungs. Erythrocytic indices are usually unchanged, but there may be terminal anemia in January disease.

CLINICAL FINDINGS
The basic syndrome associated with T. parva infection lasts for a few weeks. The incubation period is 1–3 weeks, depending on the virulence of the strain and the size of the infecting dose. Experimentally,
the first clinical sign is enlargement of lymph nodes in the area draining the site of tick attachment (i.e. 8–16 days after attachment). One or 2 days later, there is fever, depression, anorexia, and a drop in milk in dairy animals. In later stages, there may be nasal and ocular discharges, dyspnea, generalized lymph node enlargement, and splenomegaly. In severe cases, diarrhea occurs, sometimes with dysentery, but usually only late in the course of the disease. Emaciation, weakness, and recumbency lead to death from asphyxia in 7–10 days. Terminally, there is often a frothy nasal discharge. Occasional cases of brain involvement occur and are characterized by circling, hence ‘turning sickness’ or cerebral theileriosis.

In southern Africa, cerebral theileriosis is associated with an aberrant form of *T. taurontri* originating from the eland. There are localized nervous signs and convulsions, tremor, profuse salivation, and head pressing. Infection with the strain of *T. parva* (formerly *T. parva laurenseri*) responsible for Corridor disease causes a similar acute syndrome, with the additional lesion of keratitis and accompanying blepharospasm. ECF in Zimbabwe (formerly attributed to *T. parva bovis*) is generally slightly less virulent but is still frequently fatal.

**CLINICAL PATHOLOGY**

The parasites are evident as schizonts, sometimes in circulating lymphocytes, but mainly in biopsy smears of enlarged lymph nodes stained with Giemsa. Piroplasms are also easily visible in erythrocytes from day 16 after tick attachment and they increase in number until death. Over 30% of the red cells may be infected, but the level of intraerythrocytic piroplasms is not correlated with the severity of the disease. *T. parva* piroplasms are difficult to differentiate from other piroplasms, hence the necessity to find schizonts. Blood counts will reveal a panleukopenia and thrombocytopenia with little or no anemia. The protozoa can be grown on a tissue culture of lymphoblastoid cells.

A range of serological tests is available, including indirect immunofluorescent antibody test (IFAT), complement fixation test, indirect hemagglutination test, and enzyme-linked immunosorbent assay (ELISA). The ELISA test is increasingly being used for seroepidemiological studies and the polymerase chain reaction (PCR) technology is available but IFAT is the most widely used test.

**NECROPSY FINDINGS**

The most striking lesion is massive pulmonary edema, hyperemia and emphysema, along with hydrothorax and hydropericardium. Copious froth is present in the airways. The carcass is emaciated and hemorrhages are evident in a variety of tissues and organs. There is enlargement of the liver, lymph nodes and spleen, and ulceration of abomasum and intestines. Small lymphoid nodules (the so-called pseudo-infarcts) are present in liver, kidney, and alimentary track. In protracted cases, animals may have small, exhausted lymphoid organs.

Microscopic lesions are characterized by proliferating lymphoblastoid cells and varying amounts of necrosis in lymphoid organs, lungs, liver, kidneys, the gastrointestinal tract and other tissues, somewhat similar to a multicentric lymphoid tumor. Some lymphoblasts contain schizonts, which are better seen in impression smears stained with Giemsa stain. In cerebral theileriosis, infected lymphoblasts sequester in cerebral blood vessels and cause infarction.

Specimens to submit for pathology should include lymph nodes, lungs, kidneys, liver, and any other organ with gross lesions.

**DIFFERENTIAL DIAGNOSIS**

The fever, depression, and lymphadenopathy of ECF can be confused with such diseases as theileriosis due to *T. annulata*, trypanosomosis, heartwater, malignant catarrhal fever, bovine virus diarrhea, and rinderpest. The lymphoid hyperplasia may also simulate lymphoma. A knowledge of the disease history, coupled with hematological and lymph node smear examinations are usually adequate to make a definitive diagnosis.

**TREATMENT**

Once an animal is manifesting clinical signs of ECF, treatment is generally considered to be either unsatisfactory or too expensive. Tetracyclines were the recommended treatment for many years, but they have only moderate efficacy, especially if the disease has been present for a few days. Two recently introduced drugs, halofuginone lactate and parvaquone, have had a much higher success rate, but recovered animals may become carriers unless the correct dose is used. Halofuginone lactate is an effective oral treatment for the acute syndrome at two doses, 1.2 mg/kg BW. Parvaquone (10 mg/kg BW, two doses 48 h apart) or the related buparvaquone (2.5 mg/kg BW, two doses 48 h apart) given IM is effective in most cases. In field trials, buparvaquone gives results comparable to those of parvaquone and cure rates are maximized by accurate diagnosis and prompt treatment of both ECF and intercurrent infections. Cure rates are even higher if the animals are also treated for pulmonary edema with dexamethasone or the diuretic, frusemide.

**CONTROL**

Until recently, the main method of control of ECF was to break the transmission cycle between cattle and ticks. This was achieved through widespread and strict application of acaricides at 3-, 5-, or 7-day intervals throughout the year (intensive dipping), adherence to legislation on cattle movements and quarantine, and good livestock and pasture management. With the ever rising costs of acaricides, their effect on the environment, the development of acaricide resistance, and frequent political problems in the affected regions, this strategy to control ECF and other tick-borne diseases in Africa has been revised. Furthermore, it has been observed that indigenous cattle, constituting the majority of the herds in some of the affected countries, may lose their endemic stability with intensive dipping and the process is not cost-effective. An integrated approach is now advocated involving the use of genetically resistant breeds, a judicious and selective application of acaricides at 3-week intervals (strategic dipping) or when there are at least 100 ticks per animal (tactical dipping), and the use of vaccines. It was reported that monthly applications of deltamethrin-based pour-on insecticide significantly reduced the incidence of ECF and other hemoparasitic diseases in smallholder dairy farms in Kenya.

The technique used for vaccination is immunotherapy or ‘infection-and-treatment method’. Initially, cryopreserved suspensions of *T. parva* sporozoites from ground-up infected ticks were injected into the patient. Now, sporozoites from cell culture are used. The infection they cause is controlled with long-acting oxytetracycline (20 mg/kg BW IM), or preferably parvaquone given at the same time, so that premunity is established. It is preferable to use a cocktail of different stocks of parasites. Vaccination, coupled with strategic dipping only when ticks are abundant, is usually successful and economically attractive, provided local stocks of *Theileria* are included. Large-scale field trials of these vaccines are being carried out throughout East and Central Africa. Initial reports indicate that calves in high risk areas should be vaccinated at 1–2 months of age; that immunization campaigns are more efficient when concentrated in the period of low adult tick activity, and that immunization is of no benefit in herds under intensive tick control but is of high value.
when combined with strategic tick control. Strategic control plus immunization can markedly reduce the risk of clinical ECF but immunized cattle are carriers and all stages of *R. appendiculatus* can transmit infection from them to naive animals.

Limited studies have indicated that cattle could be successfully immunized without concurrent tetracycline therapy by using low pathogenicity isolates as vaccines, for example, *T. parva* (Boleni). Or infectivity sporozoite stabalized stored at −196°C for over 6 months. Because of the high cost of tetracyclines, this procedure would reduce the cost of vaccination by more than three-fold in cattle could be successfully immunized.

Because of the high cost of tetracyclines, can transmit infection from them to naive animals. ParaSites that can establish an infection, this procedure would reduce the cost of both stages, is still being investigated.

Carriers and all stages of zoite (the p67 antigen) or the schizont, or of immunizing cattle with recombinant antigens are found for the vaccine, immunotherapeutic technique and if the immunity engendered is likely to be broad, robust, and not parasite stock-specific.

**REFERENCES**

---

**TROPICAL THEILERIOSIS**

**Etiology**

*Theileria parva* is a member of the apicomplex group, like *T. parva* the cause of east coast fever. It is highly virulent for European dairy cattle. Infection in local zebu cattle is often subclinical.

**EPIDEMIOLOGY**

**Occurrence and methods of transmission**

The disease occurs from Morocco and Portugal in the west through the Mediterranean basin and the Middle East to India and China in the east. *T. annulata* affects cattle and is transmitted trans-stadally by the three-host tick *Hyalomma anatolicum* in central-western Asia and north-eastern Africa, and by the two-host tick *H. detritum* in the Mediterranean basin. The extent of its distribution may overlap with that of *T. parva* in Sudan and Ethiopia and with *T. sergenti* in the Far East. In endemic areas, virtually all adult animals are infected, but case fatality is about 10–20% and is confined mainly to calves. Exotic animals recently introduced may have 20–90% mortality. The disease occurs when there is much tick activity, mainly in summer and the rainy seasons, and in crossbred cattle. A single tick can cause fatal infection since its saliva glands usually contain numerous sporozoites. An outbreak occurred recently in a Scottish dairy farm and was believed to have been due to mechanical transmission from experimentally infected calves on a research institute associated with the farm. In the absence of natural vectors, that outbreak was quickly controlled.

**Risk factors and immune mechanisms**

The normal state is that of endemic stability. This balance is disturbed when exotic animals are introduced and heavier losses occur. Recovered animals show a solid, long-lasting immunity, but they remain as carriers. Buffaloes are believed to be the natural hosts and may also act as carriers whereas yaks are highly susceptible. As with *T. parva*, immunity is mainly cell-mediated but is poor in calves. Experimental reproduction is by feeding infected ticks on cattle or by needle inoculation of sporozoites in macerated ticks, schizonts in lymphocytes or merozoites in erythrocytes. Humans are not affected.

**Economic importance**

The disease is a major constraint to livestock improvement programs in many parts of the Middle East and Asia and about 200 million cattle are at risk.

**Biosecurity concerns**

There are none.

**PATHOGENESIS**

The life cycle of *T. annulata* is cattle-tick-
The pathogenesis therefore involves rather than in lymphocytes. Schizonts of \textit{T. annulata} invade and form schizonts mostly in macrophages/monocytes that express major histocompatibility (MHC) class II antigens, rather than in lymphocytes.\textsuperscript{6} Schizont infected cells multiply in the draining lymph nodes and disseminate rapidly throughout the lymphoid tissues and in non-lymphoid organs including the liver, kidney, lung, abomasum, and brain. Later, schizonts differentiate into merozoites and invade erythrocytes (as piroplasms). The pathogenesis therefore involves proliferation of lymphocytes and macrophages induced by schizonts and anemia with icterus induced mostly by the piroplasms. The lymphoproliferation is controlled by suppressor macrophages as a protective mechanism leading to recovery.\textsuperscript{8} Over 90\% of erythrocytes may be parasitized, each by one or more merozoites. Immunosuppression may occur in the acute phase of lymphoproliferation, but is generally less marked than in ECF,\textsuperscript{8} probably because leukocyte numbers return to normal soon after the acute phase.

**CLINICAL FINDINGS**

In a stable endemic situation, there may be only mild or no clinical disease in local zebu cattle.\textsuperscript{4} Clinical signs are acute and severe in exotic cattle and less severe in crossbreeds, and are similar to those in ECF. However, the course is longer in tropical theileriosis and may last for weeks before death. Clinical signs include marked fever, swelling of superficial lymph nodes, inappetence, tachycardia, dyspnea, pale mucous membranes and icterus. Others are diarrhea, weight loss, convulsions, torticollis and other nervous signs.\textsuperscript{5,8} In chronic cases, there may be small subcutaneous nodules from which schizonts can be demonstrated in smears.\textsuperscript{8}

**DIFFERENTIAL PATHOLOGY**

As with ECF, examination of smears of blood and lymph node biopsy will reveal piroplasms in erythrocytes and schizonts in lymphocytes. Schizonts of \textit{T. annulata} tend to be more common in the liver than in lymph node smears, but are otherwise indistinguishable from those of \textit{T. parva}. Furthemore, the piroplasms are predominately round and oval, as opposed to \textit{T. parva} which has comma and rod-shaped piroplasms. Anemia is a significant feature of tropical theileriosis, unlike in ECF, and is associated with bilirubinemia, hemoglobinuria, and bilirubinuria. The anemia results from destruction of erythrocytes containing piroplasms but other factors may include autoimmune hemolysis and poor bone marrow response. Reduction in white cell and platelet counts is less severe than in ECF, but animals dying from the disease show persistent and severe lymphocytopenia involving mainly T-lymphocytes.\textsuperscript{6}

The most commonly used serological diagnostic technique is the indirect fluorescent antibody test. For surveys, an indirect enzyme-linked immunosorbent assay (ELISA) test using a recombinant \textit{T. annulata} surface protein has been described.\textsuperscript{9} The ELISA tests provide higher sensitivity and specificity than IFAT.\textsuperscript{10}

**NECROPSY FINDINGS**

Apart from pallor of mucous membranes and yellowish discolouration of tissues, the postmortem lesions in animals dying from tropical theileriosis are similar to those of ECF. Liver, spleen and lymph nodes should be submitted for laboratory examination to detect schizonts whereas merozoites are detected in blood smears.

**DIFFERENTIAL DIAGNOSIS**

Tropical theileriosis may be confused with the other theilerioses that may occur in the region, and with babesiosis, anaplasmosis, trypanosomosis, and malignant catarrhal fever. Liver biopsy and blood examination will help to confirm a clinical diagnosis.

**TREATMENT**

Buparvaquone is the most effective agent available, and the recommended dose is 2.5 mg/kg BW.\textsuperscript{15} In calves, supportive treatment for anemia is indicated. Halofuginone at 12 mg/kg is also effective but tetracycline at 20 mg/kg is less so.

**CONTROL**

Indigenous cattle live with the disease and do not require any intensive tick control or treatment. For valuable exotic stock or the schizont. The sporozoite vaccine can be made from either the sporozoite or the schizont. The sporozoite vaccine is based on the infection-and-treatment method using schizont-infected cell lines and simultaneous tetracycline treatment as for \textit{T. parva}. It has been suggested that the most economical way to control theileriosis in India is to vaccinate calves and to reserve buparvaquone for treating clinical cases.\textsuperscript{10} The schizont vaccine was formerly blood containing a mild strain of the parasite. The newer vaccines are prepared from live schizonts grown in lymphoid cell culture and attenuated by prolonged passage. They cause virtually no adverse reactions and vaccinated cattle show good resistance to the disease for at least 3.5 years. Therefore, it is necessary to revaccinate, preferably with a different cell line vaccine, if tick population is too low to establish endemic stability. The risk for spread of the vaccine strain in the field is very low.\textsuperscript{14}

**DISEASES ASSOCIATED WITH TRYPANOSOMES**

Trypanosomes are flagellated protozoan parasites that live in the blood and other body fluids of vertebrate hosts. With the help of the flagellum, they swim in body fluids, boring their way between cells. They generally possess a kinetoplast and undergo cyclical development in an arthropod vector. Their biological adaptations, morphology, and pathogenicity are fascinating and are being extensively studied. Each of the parasites causes a disease (now termed trypanosomosis rather than trypanosomiasis) in animals and humans as summarized in Table 26.7. Trypanosomases of veterinary importance are discussed below.

**NAGANA (SAMORE, AFRICAN TRYPANOSOMOSIS, TSE TSE FLY DISEASE)**

**ETIOLOGY**

Trypanosoma vivax, \textit{T. congolense}, \textit{T. brucei brucei} and \textit{T. simiae} are the four main species responsible for African trypanosomases affecting virtually all domestic mammals. \textit{T. vivax} and \textit{T. congolense} are the main pathogens of cattle. The four species are members of the Saldavia
group of trypanosomes and are transmitted cyclically via the mouthparts of tsetse flies, hence the name salivarian trypanosomes. *T. vivax* is usually numerous in bovine blood, and can be identified by its very fast movement in wet films. In stained smears, it is a long, slender, monomorphic parasite with a rounded posterior end, a terminal kinetoplast, and a long free flagellum, but no prominent undulating membrane. *T. congolense* is smaller, sluggish in wet films, and often adheres to red blood cells by the anterior end. In stained smears, it is a short parasite with a marginal kinetoplast, no free flagellum, and no prominent undulating membrane. *T. brucei* large like *T. vivax*, but its rapid movement is in confined areas of the wet film. In stained smears, it is pleomorphic and may occur as long and slender forms, intermediate forms, or short and stumpy forms. The slender and intermediate forms have a long free flagellum, pointed posterior end, subterminal kinetoplast and a prominent undulating membrane, whereas the stumpy forms resemble *T. congolense*, but are bigger and have a prominent undulating membrane. *T. simiae* is morphologically indistinguishable from *T. congolense*, but the organism will be swarming in the blood of pigs.

**EPIEDEMOIOLOGY**

**Occurrence**

The epidemiology of African trypanosomosis is determined mainly by the ecology of the tsetse fly which is found only in tropical Africa. *T. vivax* is also transmitted mechanically by biting flies and occurs also in Central and South America. Affected countries include Bolivia, Brazil, Colombia, French Guiana, Guyana, Peru, Suriname, and Venezuela where it affects mainly cattle and sheep. 1 Whereas *T. congolense* and *T. vivax* are responsible for severe disease in cattle, sheep and goats, *T. brucei brucei* usually causes a subclinical infection in cattle, but a severe disease in sheep, goats, horses and, occasionally, pigs. *T. simiae* causes a very acute and highly fatal disease in exotic pigs. It is not pathogenic to cattle, sheep, or goats.

**Prevalence**

Infection rates in cattle in endemic areas vary considerably and could be over 60%. However, as a result of various control methods, the prevalence is decreasing in many African countries, particularly in West Africa, and was as low as 10% in Mali in the 1980s. In a 1989–1991 survey involving approximately 20,000 cattle, 3000 sheep, and 3000 goats in Nigeria, the prevalence was 4.3% in cattle, 1.6% in sheep, and 1.0% in goats, based on parasite detection. Higher prevalence rates are obtained if diagnosis is based on serology, but this does not reflect current infection. *T. vivax* and *T. congolense* are the species most frequently encountered in ruminants, but with serology *T. brucei* is also frequently reported. Mixed infections with two or three species are common. Pigs and horses are less frequently affected than ruminants, perhaps because they are less exposed to tsetse flies than cattle that normally graze over long distances. In Central and South America, *T. vivax* infections appear to be spreading to new areas where they cause periodic outbreaks of serious disease in cattle.

**Morbidity and case fatality**

Morbidity rates during outbreaks are variable and may reach 70% in cattle infected with *T. vivax* and up to 100% in pigs infected with *T. simiae*. It is usually much lower in sheep, goats, and horses since these are not often the preferred hosts for tsetse or are less exposed to tsetse challenges. Sheep and goats are more vigorous than cattle in defending themselves against successful feeding by tsetse flies. Case fatality also depends on...
parasite species, host, and its level of resistance. *T. simiae* is invariably fatal in exotic pigs. Some strains of *T. vivax* in East Africa cause similar heavy mortalities in exotic dairy cows, and infected horses are likely to die if left untreated. However, most infections in cattle in endemic areas run a chronic course and are not invariably fatal, but the animal may remain unproductive and unthrifty.

**Methods of transmission**

**Cyclical**

African trypanosomes can be transmitted by 23 species of tsetse (*Glossina*) found only in sub-Saharan Africa between latitudes 14°N and 29°S, excluding areas of high altitude, extreme drought or cold temperatures where tsetse cannot survive. Tsetse species can be grouped according to their preferred habitats as savannah species, riverine species, and forest species. The savannah species (including *G. morsitans*, *G. austeni*, *G. pallidipes*, *G. suymonteroni*, and *G. longipalpis*) pose the greatest threat to livestock because they inhabit grasslands where cattle are traditionally reared, they can easily adapt to other ecological niches, they feed primarily on cattle and pigs, and they are efficient vectors of trypanosomes. They are also the main vectors of Rhodesian sleeping sickness associated with *T. brucei rhodesiense* in humans (Table 26.7). The riverine species (*G. palpalis*, *G. tachinoides*, and *G. fuscipes*) are important as vectors of bovine and porcine trypanosomiasis, as well as of Gambian sleeping sickness due to *T. brucei gambiense*. On the other hand, the 13 or so forest species (including *G. fuscus*, *G. brevipalpis*, and *G. longipennis*) are not frequently incriminated vectors of trypanosomes even though their preferred food hosts are ruminants and suids.

The life cycle of trypanosomes in tsetse involves cyclical development for a varying length of time, depending on species and ambient temperatures. *T. vivax* completes its developmental cycle in the proboscis and pharynx and can be transmitted (as metacyclic trypanosomes) within a week of the initial infective feed. The cycle of *T. congolense* involves the midgut and proboscis and is completed in about 2 weeks. That of *T. brucei* is more complex: it takes 3 or more weeks and involves the midgut and salivary glands. Once infected, flies remain so for life (1–2 months). It follows that for any fly, its vectorial capacity and efficiency are highest for *T. vivax* and least for *T. brucei*.

**Non-cyclical**

After trypanosomes have been introduced into a herd, transmission is possible even in the absence of *Glossina*. Biting flies such as Tabanidae, Stomoxynidae, and Hippoboscidae are capable of mechanically transmitting trypanosomes in their mouth parts if they feed on more than one host within a short interval. This is how *T. vivax* is spread in areas outside the tsetse belt in Africa, as well as in Central and South America. Mechanical transmission can also occur through the needle during inoculations and in carnivores feeding on infected carcasses. Intrauterine infections occasionally occur. The carrier state

Reservoirs of infection are found in many wild animals, in trypanotolerant animals, and in chronically infected animals. Tsetse caught in and around game reserves tend to have relatively high infection rates and the relative abundance of wildlife in East Africa as compared to West Africa may explain, at least in part, why the prevalence of the disease appears to be declining more rapidly in the west.

**Risk factors**

**Host factors**

The effect of infection varies with the host in that most wild animals, and some domestic ones, establish a balance with the parasite and remain as clinically normal carriers for long periods. Specifically, some breeds of cattle indigenous to Africa can tolerate light to moderate challenge with tsetse flies by limiting the multiplication of trypanosomes in their blood and by apparently warding off the infection, especially *T. vivax*. The phenomenon is called trypanotolerance, it is both genetic and environmental in origin, and the level of tolerance varies. Thus, the indigenous taurine breeds, such as the N'Dama, Baoule and Muturu, are more tolerant than the West African zebu, and amongst East African zebu cattle, the Orma Boran and Masai zebu have superior tolerance when compared with Galana Boran and Friesian breeds. Crossbreeds of indigenous taurine and zebu animals are also more tolerant than purebred zebu. However, due to the uncertain genetic makeup of animals within these so-called breeds and crossbreeds, the level of trypanotolerance may also vary with individual animals within a given category and it can be overcome by heavy tsetse challenge, malnutrition, or other stress factors. Trypanotolerance also occurs in some indigenous breeds of small ruminants, notably the West African Dwarf sheep and goats and the East African goats, whereas the Toggenburg, British Alpine, Saanen, and Anglo-Nubian breeds of goats are fully susceptible.

**Environmental factors**

The density of tsetse population in the area, and the level of their contact with the host, will determine the level of infection. This is further influenced by the vectorial capacity of the fly and the availability of its preferred host, which may not be livestock. Trekking of cattle through tsetse-infested vegetation is a risk nomadic farmers face from time to time and the risk is even greater where cattle routes converge, for example, at major bridges or watering holes. Agricultural and industrial developments generally lead to a lowering of tsetse density by destroying its habitat, whereas the establishment of game or forest reserves provides large numbers of preferred hosts or a suitable habitat for tsetse, respectively. Herds located near such reserves are therefore at a higher risk. So also are tourists visiting game parks.

**Pathogen factors**

In cattle, *T. vivax* generally produces a higher level of parasitemia than other species. And since its life cycle in the tsetse is also shorter, *T. vivax* is more readily transmitted than the others when animals are newly introduced into a tsetse infested area. Higher parasitemias also facilitate mechanical transmission. On the other hand, *T. brucei* is rarely detectable by direct examination of cattle blood, even though infection can be confirmed through other diagnostic methods. Furthermore, some animals carry infection without showing clinical signs, especially if they are trypanotolerant like the Muturu in Nigeria, or if infected with non-pathogenic genetic types, for example, *T. congolense* kullen type in cattle.

**Immune mechanisms**

Animals recovering from infection with one strain/serodeme or species of trypanosome are not immune to infection with another strain/serodeme or species. This is due to the ability of trypanosomes to readily change their surface coat antigens through a process called *antigenic variation*. The glycoprotein surface coat is continuously shed and replaced by mechanisms not fully understood, but probably induced by antibodies. During each peak parasitemia, a mixture of variable antigenic types of parasites is present, but the dominant antigens determine the specific antibody response. These antibodies kill off the dominant population, leaving others with different dominant antigens, these multiply, and the process continues in cycles until the animal dies or the immune mechanisms catch up with the parasite and the animal recovers. This phenomenon is also responsible for the successive waves of parasitemia in infected animals. Following repeated episodes of infection and recovery (with or without treatment) in an endemic area,
animals will encounter a variety of antigenic types and therefore become less susceptible to strains/sero­demes in that area. In­fected animals are more susceptible to secondary infections by other micro­organisms, particularly bacteria. The me­chanisms involved are not fully understood, but may vary with the species of animals. In ruminants, the state of immuno­suppression is abrogated once the trypano­somes are eliminated by chemotherapy.

**Experimental reproduction**

Infection can be easily reproduced by inoculation of infected blood or other body fluid into a susceptible host. Infected flies can also be fed on the host to transmit the disease. Several laboratory animal models are available and lots of studies are done with mice and rats.

**Economic importance**

Tsetse flies infest 10 million square kilometers of Africa involving 37 countries. Hence, nagana is today the most important disease of livestock in the continent. The added risk of human infections has greatly affected social, economic, and agricultural development of rural communities. Since nagana is a wasting disease, affected animals are chronically unproductive in terms of milk, meat, manure, and traction, and the mortality rate can be high. The disease in Africa costs livestock producers and consumers an estimated US$1340 million each year. The anticipated losses due to *T. vivax* in South America exceed $160 million. Furthermore, the disease may impact on various immunization campaigns in endemic areas due to the fact that it can cause immunosuppression.

**Zoonotic implications**

The animal pathogens do not infect humans, but animals can serve as reservoirs of *T. brucei rhodesiense* and *T. brucei gambiense*, the causes of human sleeping sickness, which are morphologically indistinguishable from *T. brucei brucei*. Human infections result from tsetse bites, generally in game parks, forest reserves, and along streams or other rural setting. The incidence has fallen greatly since the early part of the 20th century, but outbreaks still occur from time to time, especially when civil unrests force people into tsetse-infested areas. Up to 100 000 cases are reported per year and *T. brucei gambiense* sleeping sickness has re­emerged as a major public health problem in Central Africa, especially in the Democratic Republic of the Congo, Angola, and Southern Sudan, where civil wars have hampered control efforts.

A rash (chancre) develops at the site of tsetse bite and this is soon followed by fever, persistent headache, and swelling of lymph nodes, spleen, and liver. Weakness and signs of cardiac involvement may be noticed early in the Rhodesian form and the disease is rapidly fatal. The Gambian form is more chronic, lasting for 3 or more years during which the patient gradually wastes away or dies from secondary infection. The parasite invades the cerebrospinal fluid leading to progressive non-suppurative meningoencephalitis which causes the patient to fall asleep often, hence the name sleeping sickness.

**Biosecurity concerns**

There are none because the vector requires strict environmental conditions to survive. People working with *T. b. gambiense* and *T. b. rhodesiense* should take precautions to avoid accidental inoculation of themselves or their co-workers with infected material in syringes or tsetse flies.

**PATHOGENESIS**

Nagana in most species is a progressive, but not always fatal disease and the main features are anemia, tissue damage, and immunosuppression. Metacyclic trypano­somes are inoculated intradermally as the fly feeds. They multiply at this site provoking a local skin reaction (chancre), which is most pronounced in a fully susceptible host and may be slight or absent with some strains or species of trypanosomes. Within the chancre, metacyclic parasites change to trypanostigate form, enter the bloodstream directly or through the lymphatics, and initiate characteristic intermittent parasit­emias. Their behavior thereafter depends largely on the species of trypanosome transmitted and the host. *T. vivax* usually multiplies rapidly in the blood of cattle, sheep and goats, and is evenly dispersed throughout the cardiovascular system, whereas *T. congolense* tends to be aggregated in small blood vessels and capillaries of the heart, brain, and skeletal muscle, and rarely causes heavy parasit­emias in ruminants. Both species exert their effect mainly by causing severe anemia and mild to moderate organ damage. The anemia has a complex pathogenesis involving mainly increased erythro­phagocytosis, some hemolysis, and dys­hemopoiesis. Very acute infections with *T. vivax* in cattle or *T. simiae* in pigs result in fulminating parasit­emias and disseminated intravascular coagulation with hemor­rhages. Such syndromes resemble a septicemia, and anemia may not be severe. *T. brucei* and, rarely, *T. vivax*, have the added capability of escaping from capil­laries into interstitial tissues and serous cavities where they continue to multiply. Such infections result in more severe organ damage in horses, sheep, and goats, in addition to anemia. The cerebrospinal fluid is often invaded by *T. brucei* alone or mixed with other species, or as a relapse after an apparently successful treatment.

Animals chronically infected with any pathogenic trypanosome may develop concurrent and even fatal bacterial, viral, and other protozoan infections as a result of immunosuppression. Pregnant animals may abort, and transplacental fetal infections occasionally occur. Trypano­tolerant animals control parasit­emias better and have less severe anemia and organ damage. They usually recover from the disease, but may act as carriers.

**CLINICAL FINDINGS**

There are no pathognomonic signs that would help in pinpointing a diagnosis. The general clinical picture is as follows but there are many variations determined by the level of tsetse challenge, the species and strain of the trypanosome, and the breed and management of the host. Acute episodes last for a few days to a few weeks from which the animal dies or lapses into a subacute to chronic stage, or the illness may be chronic from the beginning. Chronic cases may run a steady course, may be interrupted by periodic incidents of severe illness, or undergo spontaneous recovery.

The basic clinical syndrome appears after an incubation period of 8–20 days. There is fever, which is likely to be intermittent and to last for a long period. Affected animals are dull, anorexic, apathetic, have a watery ocular discharge, and lose condition. Superficial lymph nodes become visibly swollen, mucous membranes are pale, diarrhea occasionally occurs, and some animals have edema of the throat and underline. Estrus cycles become irregular, pregnant animals may abort, and semen quality progressively deteriorates. The animal becomes very emaciated and cachectic and dies within 2–4 months or longer. Thin, rough-coated, anemic, lethargic cattle with generalized lymph node enlargement are said to have a 'fly-struck' appearance.

In general, *T. congolense* is more patho­genic to cattle in eastern and southern Africa, whereas *T. vivax* produces a more serious disease in West Africa. However, severe outbreaks of *T. vivax* involving exotic dairy animals in East Africa occur; affected animals show mucosal petechiation, rhinorrhagia, dysentery, and death after an illness of only a few weeks. Mixed infections are common and are usually more severe. Furthermore, intercurrent bacterial, viral, or other parasitic infections may mask or complicate the basic clinical syndrome. Immune response to bacterial, and some viral, vaccines is also depressed but is restored if trypanocidal therapy is given at the time of vaccination.
Clinical findings peculiar to the individual trypanosome are as follows:

- *T. vivax* affects all agricultural species except pigs. Acute and chronic outbreaks occur, anemia is severe, and fever is usually associated with high parasitemia. A chronic form of the disease is more usual in East Africa, but an acute hemorrhagic form can occur with exotic cattle. *T. vivax* is less commonly seen in trypanotolerant cattle breeds.

- *T. congolense* affects all species, usually with an acute disease lasting 4–6 weeks, but some chronic cases occur, especially in West Africa. Anemia and emaciation are severe.

- *T. brucei* affects all species with a subacute to chronic disease in which subcutaneous edema and keratoconjunctivitis may be marked. Nervous signs are manifested in horses, pigs, and small ruminants by ataxia, circling, head pressing, and paralysis. Cattle are usually asymptomatic, with few exceptions.

- *T. simiae* affects exotic pigs with a fulminating infection in which the animal dies within hours or a few days of first appearing ill. There is fever, stiff gait, dyspnea, and cutaneous hyperemia, but no significant anemia.

### CLINICAL PATHOLOGY

The anemia results in a progressive drop in packed cell volume, a non-specific but useful indicator in endemic areas. The classic method of confirming diagnosis is to demonstrate parasites in a wet blood film, and in a thin or thick blood smear stained with Giemsa. This is easiest in the early stages of the disease when parasitemic peaks correspond with fever. As the disease progresses, parasitemias become infrequent and the intervals between peaks grow longer, even though the animal is still sick. To increase the accuracy of parasitological diagnosis, it is now routine to concentrate the parasites in theuffy coat layer of a microhematocrit capillary tube. The buffy layer is then examined directly at low power (Woo's method) or in a wet preparation with a dark ground/phase contrast microscope (Murray's method). Both tests are simple, sensitive, and applicable to field use on individual animals as well as in herds. Blood should be examined fresh but may be refrigerated for up to 24 hours, beyond which most parasites will die and disappear from the sample.

In chronic cases, blood can also be inoculated into experimental animals, usually rodents, but this is cumbersome and is accurate for only *T. brucei*, and possibly *T. congolense*, but not *T. vivax*.

Another alternative is a series of standard serological tests to detect anti-trypanosome antibodies in sera or other body fluids. The three tests used most often are the indirect immunofluorescent antibody test (IFAT), the capillary agglutination test (CAT), and the ELISA. These tests have the disadvantage that they indicate past as well as present infections, are difficult to standardize for different laboratories, and are not species-specific. The ELISA technique was modified to detect circulating trypanosome antigens (antigen-ELISA) using monoclonal antibodies that would distinguish between *T. vivax*, *T. congolense*, and *T. brucei*, and would detect only current or very recent infections. Extensive field trials in Africa and the Caribbean have shown that the test is not sufficiently sensitive or specific and that it needs to be combined with other parasitological methods to provide reliable results.

The polymerase chain reaction (PCR) technique can be used to detect trypanosome DNA in body fluids and in blood. The test is sensitive and species specific and can be combined with ELISA. Under experimental conditions, it can also be used to monitor therapy, especially relapses, since treated animals should become PCR negative 1–2 days after treatment. It is also possible to do retrospective epidemiological surveys using serum banks. Dried blood spots on filter papers are also a useful source of DNA for the detection of *T. congolense* and *T. brucei* by PCR. But the test is expensive and can only be done in specialized laboratories.

### NECROPSY FINDINGS

**Gross pathology**

The postmortem lesions are, like the clinical findings, not definitive. The carcass is marked by anemia, emaciation, anasarca, and enlargement of the liver, spleen, and lymph nodes. Body fat stores are depleted or show marked serous atrophy, especially around the heart and in bone marrow. There may be corneal opacity and testicular degeneration. In acute cases, there will be a general congestion of the viscera and extensive hemorrhages in all tissues. Chronic cases show cachexia, often complicated with secondary bacterial or other parasitic diseases.

Microscopic lesions are also not specific, except in very acute infections in which clumps of trypanosomes mixed with fibrin thrombi are found in blood vessels. Lymphoid organs are usually hyperplastic and may show varying degrees of erythrophagocytosis or hemosiderosis. Bone marrow macrophages may engulf red cells as well as other immature and mature cells. The interstitial tissues of various parenchymatous organs may contain a lymphoplasmacytic infiltrate. This tends to be most marked with *T. brucei* in which the parasites often localize extravascularly in the intestinal tissue. A severe non-suppurative meningoencephalitis or myocarditis may result. Degenerative changes may also be present in the liver, testis, and puititary gland.

### TREATMENT

The number of trypanocidal drugs available for treating and preventing infections in endemic areas is limited, and about 6 million doses are administered yearly in Africa. The drugs have been in the market for over 30 years, their range of therapeutic safety is small, many of them cause severe local reactions especially in horses, and some may be fatal in high doses. Furthermore, as drugs are not always available and they are expensive, underdosing is common. These, plus the fact that some drugs are used both prophylactically and therapeutically, have led to cases of drug resistance.
Ideally, each country or region establishes a group of sanative drugs which are to be used only as a break in a course of one of the more common drugs. The sanative drug should provide moderate prophyaxis and avoid the development of resistance to the prime drug. These measures have not been well-executed in many countries and this may explain the increasing reports of multiple resistance to curative, sanative, and prophylactic drugs. Nevertheless, the prevalence of drug-resistant trypanosomes in the field still remains unclear as there are no suitable methods for the detection of resistant field isolates. For example, drug resistance has been reported to be very low in eastern Zambia but widespread in Burkina Faso and Ethiopia.

Strains are regarded as resistant when they fail to respond to the drug or when they relapse some time after an apparent cure. Relapses are more likely to occur if the commencement of treatment is delayed or the dose rate is inadequate. However, in field situations, there is hardly any regular monitoring of drug efficacy and animals may be reinfected with the same or other species of trypanosomes soon after an otherwise effective cure.

The common drugs in use against trypanosomes are set out below. The specific dose rates vary with animal species, the specific trypanosome, and the specific purpose (curative, prophylactic, or sanative). Diminazene aceturate (Berenil) is used widely against T. vivax and T. congolense as a curative and sanative drug at 3.5–7 mg/kg BW. It is well-tolerated by ruminants and it is one of the two recommended drugs for bovine trypanosomosis. It is not well-tolerated by horses.

Homidium bromide (ethidium) and homidium chloride (novidium) are also widely used against T. congolense and T. vivax as curative and sanative drugs at 1 mg/kg BW.

Isometamidium (Samorin or Trypamidium) is the other preferred drug against T. vivax and T. congolense in ruminants. It is used as a curative and prophylactic drug at 0.25–1 mg/kg BW. At much higher doses (12.5–35 mg/kg BW) it can be used prophylactically against T. simiae in pigs but without the risk of death from acute cardiovascular collapse.

Pyrithidium bromide (prothridium) is less widely used against T. congolense and T. vivax as prophylaxis at 2 mg/kg BW.

Antricyde-Suramin complex is the other preferred prophylactic drug at 7.4 mg/kg BW for trypanotolerant animals. Quinapyramine sulfate and chloride (Antricyde) is used prophylactically at 7.4 mg/kg BW.

Suramin (naganol) may also be used against T. brucei as a curative and prophylactic drug at 10 mg/kg BW in horses and camels.

Antricyde–Suramin complex is the only other drug against T. simiae in pigs and it is used prophylactically at 40 mg/kg BW.

**CONTROL**

The control of trypanosomosis in enzootic countries involves control of tsetse fly population, prophylactic treatment, good husbandry of animals at risk, and use of trypanotolerant animals. There is no vaccine against the disease and, in spite of intensive research, none appears likely in the near future because of the ability of trypanosomes to readily change their glycoprotein surface coat through a process called antigenic variation.

Control of tsetse has been successfully attempted in some African countries, but reinvasion is frequent if the land is not properly utilized. The earliest methods involved bush clearing and elimination of game animals on which tsetse feed. These methods were effective in eradicating or controlling tsetse in some parts of the continent, especially in southern Africa, but they resulted in destroying valuable plant and animal resources, and also led to soil erosion. More recent methods involved the use of insecticides, especially DDT and endosulfan, applied strategically in the form of ground and aerial spraying over large expanses of land. As tsetse are sensitive to insecticides and no resistance has developed, considerable successes were achieved in some countries. However, spraying insecticides is costly and harmful to the environment. These harmful effects are considerably reduced if the insecticides, for example, synthetic pyrethroids, are applied directly on the animal in the form of spray or pour-on formulation. The latter offers great promise and also reduces tick infestation in treated animals.

Other effective methods involve targets impregnated with insecticides and traps that attract and catch tsetse. These are simple and cheap and can be constructed and maintained by local communities. Furthermore, they do not pollute the environment and are suitable for both small- and large-scale farming. They have been used to reduce tsetse fly population by over 97% within 7 months in a community in the Congo and to greatly reduce the incidence of trypanosomosis in another community in southwestern Kenya over a 12-year period.

Another method is the sterile male technique. Since the female tsetse only mates once in a lifetime, this technique is theoretically able to eradicate a targeted tsetse species in areas where other methods have been used to reduce its density. But it is expensive. Finally, it should be stated that development of the land for agriculture, industries, highways, etc. will effectively destroy the habitat for tsetse flies. This has occurred significantly in Nigeria where there were rapid economic activities and expanding human population in the 1970s and 1980s.

Attempts at trypanosomosis control have also been directed to prophylactic dosing with chemicals such as suramin, prothridium, and isometamidium (Samorin). Prophylaxis is used along with other methods in areas where there is a heavy tsetse challenge. The prophylactic effect is supplemented by the development of antibodies, and the total period of protection may be as long as 5 months. However, it is customary to give four or five treatments per year. The productivity response to this pattern of treatment is good if general husbandry is also adequate. The downside of this approach is that it has reportedly led to drug resistance in many countries.

Trypanotolerant animals are being used to establish ranches in areas where tsetse challenge is not too heavy, but they have not been readily accepted in some countries, supposedly because they are smaller in size and they produce less milk than other indigenous breeds and crosses with exotic breeds.

For effective control of trypanosomosis in Africa and in Central and South America, an integrated approach will mostly likely produce the desired results in each region. In the absence of a vaccine, control methods must combine reduced exposure to the vectors (large scale tsetse trapping and pour-on applications) with strategic treatment of exposed animals (chemotherapy and chemoprophylaxis) along with use of trypanotolerant animals when feasible.

**REVIEW LITERATURE**

ETIOLOGY

Trypanosoma evansi, the first pathogenic trypanosome to be identified in 1880 in India, belongs to the *brucei* group (subgenus *Trypanozoon*) but is not capable of cyclical development in tsetse *Glossina* spp. In blood smears, *T. evansi* is morphologically indistinguishable from *T. brucei*, but at the molecular level, the structure of the kinetoplast DNA of *T. evansi* is different.

*T. evansi* in South America is now accepted as a dyskinetoplastic variant of *T. evansi* rather than a separate species.

**EPIDEMIOLOGY**

**Occurrence**

Sura is a widespread distribution in areas of Africa north of the tsetse belt and in the Middle East, Asia, and Central and South America. The disease in South America is called 'mal de caderas' or 'murrina'. In some countries, the incidence of surra increases significantly during the rainy season when there are large biting fly populations, the so-called 'sura season'. The disease affects mainly camels and horses, but buffaloes and cattle are also affected. In South America, surra has not been reported in New World camelds, even though they are susceptible.

**Morbidity and case fatality**

Infection rates of 20% are not uncommon in camels living in the northeastern parts of Africa, and they can be as high as 70%.

The case fatality in horses and camels is nearly 100% if untreated, but is much lower in cattle and buffalo where the disease tends to run a chronic course.

**Method of transmission**

Several hematophagous flies can transmit *T. evansi* mechanically, but the most important is the horse fly (*Tabanus* spp.), followed by the stable fly (*Stomoxys* spp.). Transmission is enhanced when horses or camels congregate or are closely herded and when they have high numbers of parasites in their blood. In South America, the vampire bat also transmits the disease in its saliva. The process can be mechanical as for flies but also biological in that parasitemia occurs in the bats which may die from the infection or recover and serve as carriers. Therefore, vampire bats are simultaneously hosts, reservoirs, and vectors of *T. evansi*.

Carnivores can also be infected perorally when they feed on an infected carcass.

Indigenous cattle, buffalo, and several species of wildlife may act as reservoirs of infection for horses and camels. Immune mechanisms are related to antigenic variation of the parasite and the production of antibodies by the host, as in *T. brucei*. The disease can be reproduced experimentally by blood inoculation. Humans are not susceptible.

**Economic importance**

Sura is one of the most important diseases of camels. Camel raising in Africa and buffalo production in Asia are severely affected by the disease. As in nagana, losses are due to reduced productivity, mortality, and cost of treatment. In Indonesia, surra is ranked as the third most important livestock disease, with losses in 1984 estimated at more than US$20 million.

**Biosecurity concerns**

There are none.

**PATHOGENESIS**

Trypanosomes are inoculated into the host from the contaminated mouthparts of biting insects or the saliva of vampire bats. Parasite multiplication in the blood and body fluids causes inflammatory changes and anemia just like *T. brucei*. The parasite frequently localizes extravascularly in tissues including the central nervous system where it is less exposed to chemotherapeutic agents.

**CLINICAL FINDINGS**

The main clinical findings are intermittent fever, progressive anemia, edema of the feet, and infections of the central nervous system.
CLINICAL PATHOLOGY
As with T. brucei, parasite detection including the buffy coat method is easier in the acute phase. In the chronic phase, repeated sampling for some days may be required. In addition, suspected blood samples may be inoculated into rats or mice both of which are highly susceptible. A number of non-specific serological tests can also be used but are more reliable in areas where other forms of trypanosomosis do not exist. These include mercuric chloride, formol gel, or stilbamidine test for increased serum protein levels. Specific antibody detection tests are also available, but await large-scale evaluation and standardization. They include direct card agglutination test (CAAT) for antibodies, the latex agglutination test (Suratek) for circulating antigens, the indirect fluorescent antibody test (IFAT), and the enzyme-linked immunosorbent assay (ELISA). In a study in Kenya, CAAT and Suratex were reported to be more sensitive than parasitological methods in revealing the true extent of surra in camel herds, contrary to an earlier study from Chad. Techniques involving the polymerase chain reaction (PCR) have been described; they are more sensitive and specific, but too expensive for routine use.

NECROPSY FINDINGS
The carcass is emaciated and pale and may be icteric but, as in T. brucei infections, there are no pathognomonic gross and microscopic lesions. However, a lymphoplasmacytic infiltrate of various organs, including the brain and spinal cord, is characteristic. Parasites are detectable in body fluids if the carcass is fresh. Tissues for laboratory examination should include blood, brain, lymph nodes, spleen, and liver.

Differential Diagnosis
Laboratory services are required to confirm a diagnosis, and even then surra cannot be easily distinguished from T. brucei infection where both coexist. Clinical signs and gross and microscopic lesions of both diseases in horses and camels are identical.

TREATMENT
Drugs used for treating nagana could be used for surra, but the outcome is less favorable owing to their low trypanocidal activity against T. evansi and their specific toxicity for camels and horses. Furthermore, the drugs are not able to cross the blood–brain barrier to reach parasites in the cerebrospinal fluid and nervous tissue. As a result, drug resistance readily occurs, especially if the accurate dose is not given.

Quinapyramine sulfate (quinticine) is used curatively for camels, and diminazene aceturate (Berenil) for horses and camels. On the other hand, quinapyramine prosalt (trypacide), suramin (naganol) and isometamidium chloride (samorin or trypancid) are used both curatively and prophylactically. The new drug is a water-soluble arsenical, RM110 or Cymerlasan (melarsomine), given SC at 0.3–0.6 mg/kg BW. It is as effective as berenil in infected camels.

CONTROL
Unlike in nagana, control measures are aimed primarily at the host rather than the vector, which is abundant. The measures include detection and treatment of infected animals, prophylactic treatment of susceptible animals, and their protection from biting flies and bats, where possible. As in nagana, there is no vaccine.

DOURINE (MALADIE DU COIT)

ETIOLOGY
Trypanosoma equiperdum
Clinical signs
Primary genital signs, secondary cutaneous signs and tertiary nervous signs.

Epidemiology
Venereal disease of horses, mules, and donkeys, endemic in southern and northern Africa, Asia, and possibly South and Central America.

Pathogenesis
Transmission during copus → infection of genital mucosa → parasitemia → localization in skin and nervous system → edema and nervous signs.

Clinical pathology
Serosal, rarely parasite detection in edema fluid and blood.

Lesions
Edematous swelling and later, depigmentation of external genitalia, ecchymosis, anemia and subcutaneous edema.

Differential diagnosis list
- Nagana
- Surra
- Coital exanthema
- Equine infectious anemia.

Treatment
Chronic cases unresponsive to trypanocides and they often become carriers.

Control
Elimination of reactors, control of breeding and movement of animals in affected regions or countries.

EPIDEMOLOGY
Occurrence
Dourine is endemic in northern and southern Africa and Asia, and possibly South and Central America. However, it has not been reported in Latin America for over 15 years, possibly due to very strict international regulations which tend to discourage official notification of the disease.

Dourine has been eradicated from North America and there are no recent reports of outbreaks in Europe.
probably because of strict control measures. It is rare in sub-Saharan Africa, other than Ethiopia and Namibia. All Equidae are susceptible and natural infection is known to occur only in horses, mules and donkeys.

Measures of disease occurrence
The prevalence of dourine has declined generally since the horse is no longer that important militarily, economically, and agriculturally, and because of strict control measures in many countries. Recent reports, based on clinical signs and serology, indicate a prevalence in some herds to be as high as 7% in Mongolia, 28% in Ethiopia, and 29% in Namibia. In South and Central America and in Europe, the disease occurs sporadically. Case mortality rate varies; in Europe it could be as high as 50–75%, but is much less elsewhere although many animals may have to be destroyed as a means of control.

Methods of transmission
Natural transmission occurs only by coitus, but infection can also be acquired through intact oral, nasal and conjunctival mucosae in foals at birth. The source of infection may be an infected stallion or mare actively discharging trypanosomes from the urethra or vagina, or an uninfected male acting as a physical carrier after serving an infected mare. The trypanosomes inhabit the urethra and vagina, but disappear periodically so that only a proportion of potentially infective matings result in infection. Invasion occurs through intact mucosa, no abrasion being necessary.

Risk factors
*T. equiperdum* is incapable of surviving outside the host and, like other trypanosomes, it dies quickly in cadavers. Some animals may be clinically normal but act as carriers of the infection for many years. Since the disease does not require an arthropod vector for its transmission, and in view of the extensive movement of horses across continents that now takes place, the risk of infection, though small, is present in every country, as with any other venereal disease. Thoroughbred horses are more susceptible than indigenous horses, and donkeys tend to show more chronic signs.

Immune mechanisms
Infected animals produce antibodies to successive antigenic variants, as in *T. brucei*. Recovered animals often become carriers. Blood from infected horses is rarely infective to other horses, and the disease is not easily transmitted to ruminants under experimental conditions. Humans are not affected.

Biosecurity concerns
There are none.

**PATHOGENESIS**
*T. equiperdum* shows a remarkable tropism for the mucosa of genital organs, the subcutaneous tissues, and the peripheral and central nervous systems. Trypanosomes deposited during coitus penetrate the intact genital mucosa, multiply locally in the extracellular tissue space, and produce an edematous swelling which may later undergo fibrosis. Subsequent systemic invasion occurs and localization in other tissues causes vascular injury and edema, manifested clinically by subcutaneous edema. Invasion of the peripheral nervous system and the spinal cord leads to incoordination and paralysis.

**CLINICAL PATHOLOGY**
Trypanosome detection is difficult, but should be attempted in edema fluid, subcutaneous plaques, and vaginal or urethral washings or blood in early stages. Inoculation of blood into laboratory rodents is not as helpful as with other members of the brucei group. An efficient complement fixation test (CFT) is available and was the basis for a successful eradication program in Canada, but there are discrepancies in some of the CFT results. Other serological tests that can be used include the indirect fluorescent antibody test (IFAT), the capillary agglutination test for trypanosomes (CATT), and the enzyme linked immunosorbent assay (ELISA), but the CFT remains the most reliable. Serological tests do not distinguish between members of the *brucei* group and hence they are of limited value in areas where *T. brucei* or *T. evansi* is endemic, even when monoclonal antibodies are used. The polymerase chain reaction (PCR) has been used to detect trypanosome DNA and is an indication of an active infection, unlike the CFT which detects past and current infections. But the PCR test cannot yet distinguish strains of *T. equiperdum* from clinical cases that have appeared in various parts of the world since 1982. Therefore, new internationally recognized tests for the diagnosis of dourine are needed urgently.

**NECROPSY FINDINGS**
Emaciation, anemia, and subcutaneous edema are always present, and edema of the external genitalia may be evident or the external genitalia may have healed, leaving the characteristic depigmented scars of permanent leukodermic patches. Lymph nodes are enlarged and there is softening of the spinal cord in the lumbosacral region.

Histological lesions consist of lymphoplasmyacytic infiltration in the spinal nerves, ganglia, and meninges of the lumbar and sacral regions, and in affected skin and mucosa. Trypanosomes can be found in sections of the skin and genital mucosa during the primary and secondary phases of the infection.
Affected lymph nodes show non-specific lymphoid hyperplasia.

DIFFERENTIAL DIAGNOSIS

The full clinical syndrome is diagnostic, when present, since no other disease has the clinical and epizootiological characteristics of dourine. However, when the full clinical picture is not developed, other diseases like nagana, surra, coital exanthema, equine infectious anaemia, and purulent endometritis should be considered. Recent reports of the disease have been based on clinical signs, serology and detection of trypanosome DNA, but not on parasitological detection.

TREATMENT

Many trypanocidal drugs have been used in the treatment of dourine, but results are variable, chronic cases in particular being unresponsive to treatment. Berenil (diminazene) at 7 mg/kg BW as a 5% solution injected IM, with a second injection of half the dose 24 hours later, or suramin (10 mg/kg IV for two to three treatments at weekly intervals), or quinapyramine sulfate (3–5 mg/kg in divided doses injected SC) have been tried. The main drawback is that treated animals may remain inapparent carriers.

CONTROL

In dourine-free countries, an embargo should be placed on the importation of horses from countries where the disease is endemic, unless the animals have been properly tested and found negative. Eradication on an area or herd basis is by the application of the CFT, along with strict control of breeding and movement of horses. Positive reactors are disposed of, and two negative tests not less than a month apart can be accepted as evidence that the disease is no longer present. Castration or neutering of infected animals is not adequate because mating can still occur.

### Nematode Diseases of the Alimentary Tract

#### Parasitic Gastroenteritis in Ruminants

**Synopsis**

**Etiology** The nematode genera Trichostrongylus, Ostertagia (including Teladorsagia), Cooperia, and Nematodirus.  
**Epidemiology** Transmission is by ingestion of infective larvae. Disease risk is determined by factors influencing the susceptibility of the host, the numbers of larvae ingested, and the numbers of larvae undergoing hypobiosis within the host. Calves and lambs are most vulnerable, as are goats of all ages. Type I disease follows recent infection, Type II disease is delayed until hypobiotic larvae resume development.  
**Signs** Diarrhea and weight loss, production losses.  
**Clinical pathology** High fecal egg count (in young animals) (unless disease caused by immature worms), elevated plasma pepsinogen and gastrin concentrations (in abomasal infections only).  
**Lesions** Raised nodules on gastric mucosa and/or inflammation and villous atrophy in anterior small intestine.  
**Diagnostic confirmation** Worm counts at necropsy, otherwise largely reliant on clinical signs and history. Fecal egg counts and plasma pepsinogen concentrations confirmatory in some instances.  
**Treatment** Avermectins/milbemycins, benzimidazoles/probenzimidazoles; levamisole and morantel. Not all compounds are suitable for controlling hypobiotic larvae.  
**Control** Methods differ widely according to climatic region and management. The major aim is to maintain safe grazing by reducing pasture contamination. Integrated management schemes which reduce dependence on drug usage are preferred, particularly in sheep and goats.

#### Etiology

The nematode genera Trichostrongylus, Ostertagia, Cooperia, and Nematodirus (known locally as scour worms or hair worms) often occur together in the alimentary tract of ruminants. Their combined effects on the host, together with those of other alimentary nematodes such as Oesophagostomum and the hookworms, are commonly known as parasitic gastroenteritis (PGE). The main species are listed in Table 27.1 together with their hosts and anatomical preferences. The listed worms are from the same nematode family and are collectively known as the trichostrongylids. Haemonchus also belongs to this group but is considered separately as the disease processes it provokes are more complex. Taxonomists now believe that the Ostertagia species of sheep should be assigned to a different genus, Teladorsagia and Nematodirus to a different family, but the clinical convenience of the older nomenclature has been retained for the purposes of this chapter. Related species from other hosts, for example Ostertagia leptospicularis from deer, sometimes cause disease outbreaks in cattle.  

#### Lifecycle

The trichostrongylids all have direct lifecycles (i.e. there is no intermediate host). Eggs passed in the feces hatch under suitable environmental conditions, producing two non-parasitic larval stages and then the infective third-stage larva. This is ensheathed, i.e. it retains the shed cuticle from the previous molt for protection. The eggs of Nematodirus spp. are different from the others. They are larger and do not hatch initially. Instead, an infective ensheathed larva develops within the egg thereby gaining even greater resistance to harsh environmental conditions. When infective trichostrongylid larvae are ingested by the host, they esheath and depending on species, enter either the gastric glands of the abomasum or the crypts of the small intestine. Here they molt, return to the lumen and
after a fourth molt mature to become adult. The time from ingestion of larvae to appearance of egg-laying females (the prepatent period) normally takes about 3 weeks, except for Nematodirus, which takes a week or so more. This period may become extended as third- or early fourth-stage larvae, depending on species, can become arrested in development (hypobiotic) thereby delaying emergence from the mucosa for weeks or months.

Hypobiosis is probably an adaptation phenomenon similar to diapause in insects and happens during periods of adverse pasture conditions. For example, strains of O. ostertagi from northern Europe, the northern United States, and New Zealand undergo hypobiosis in autumn with worms resuming development in spring, while strains in the southern United States and Australia hypobiose in spring to emerge after the dry season in autumn.\(^2\) Thus, hypobiosis ensures that a new generation of adults is ready to lay eggs when the external environment again becomes favorable. The environmental stimuli that condition infective larvae to become hypobiotic in the host vary with species and locality, and in most cases are unknown. For O. ostertagi in Europe, exposure of infective larvae to low temperatures in the autumn is the trigger. The proportion of ingested larvae becoming arrested varies greatly with locality and, in some places, also from year to year.

\(^1\)Trichostrongylus axei also occurs in the stomach of horses.
\(^2\)The genus name Teladorsagia is often used in place of Ostertagia for these species.

### EPIDEMIOLOGY

Natural trichostrongylid infestations mostly comprise a mixture of species. The relative importance of each varies with locality and season. In sheep and cattle, Ostertagia tends to be of greatest clinical significance in winter rainfall areas while Haemonchus is predominant in summer rainfall zones. Other genera may dominate in some areas or under some management practices. Sheep and goats share many trichostrongylid species but cross-infection between sheep and cattle occurs only to a limited extent. Patterns of disease are determined by factors influencing the susceptibility of the host, the numbers of infective larvae accumulating on the pasture and the numbers of larvae undergoing hypobiosis in the host.

Resistance to trichostrongylid infections is complex and involves genetically determined physiological and acquired immunological components. Age resistance is seen particularly in the case of Nematodirus, where 3 to 4-month-old lambs are better able to withstand larval challenge than younger animals. Differences in susceptibility occur between breeds and between individuals within a group.\(^3\) Acquired immunity in sheep and cattle develops quickly after exposure to Nematodirus but takes much longer with other gastrointestinal trichostrongylids. Consequently, disease associated with Nematodirus is only likely to occur at first exposure, but animals remain susceptible to the other trichostrongylids for most or all of the first grazing season. In cattle, exposure to Cooperia leads to immunity earlier in the season than is the case with Ostertagia.\(^4\) Lambs can develop high resistance to Trichostrongylus by about 6 months of age when larval intake is high, but this period is extended when challenge is low.\(^5\) Immunity may be expressed as:

- A reduction in parasite numbers
- Stunted surviving worms
- Lowered egg output by females
- A smaller establishment of incoming larvae.

The term 'resilience' is used to describe the ability of an animal to withstand the damaging effects of parasitic infestation (as distinct from limiting worm numbers). Resistance and resilience can be affected adversely by stress and nutritional deficiencies. Moderate infestations can be tolerated by animals on a good plane of nutrition when similarly infected but poorly nourished animals would succumb. In weaner lambs, the reduction of food intake at weaning increases susceptibility, while the poor quality of winter feed has the same effect in older stock. Massive infestations can overwhelm even well-fed animals.

A relaxation in immunity to trichostrongylid infection occurs in sheep but not cattle before or at the time of parturition and reaches a peak 6–8 weeks after lambing. This happens because priority is given for allocation of scarce metabolizable protein to milk production over immune functions.\(^6\) As a result, ewes pass large numbers of worm eggs onto the pasture over a period of several weeks. This is known as the periparturient egg rise (PPER) and is an important source of pasture contamination.

Nematodirus spp. behave differently from other trichostrongylids. This genus does not contribute to the PPER in ewes and so lambs are the sole source of contamination on sheep pastures. Nematodirus eggs containing the infective third-stage larvae hatch only after exposure to specific stimuli, particularly warmth after a period of low temperatures. Thus, most hatch in the spring of the year following that in which they were deposited (although a proportion may hatch in the autumn of the first year).\(^7\) Unlike the other trichostrongylids, therefore, Nematodirus is transmitted from one lamb crop to the next. N. battus is more pathogenic than the other species because its hatching requirements are more precise. This results in many eggs hatching simultaneously to produce a sudden overwhelming wave of pasture contamination.
The eggs and free-living larvae of *Trichostrongylus*, *Ostertagia*, *Cooperia*, and *Nematodirus* can survive and develop at much lower temperatures than those of *Haemonchus*. The eggs and larvae of *Ostertagia* and *Nematodirus* are particularly resistant to cold temperatures. The eggs of the latter worm contain trehalose, which acts as an antifreeze. All these trichostrongylids can survive a moderate winter but the spectrum of endemic species declines as regional winter conditions become more severe. Snow cover however protects infective larvae from extreme cold. Upper temperature limits for survival are also lower than for *Haemonchus* and this is why the clinical importance of *Ostertagia* spp. diminishes in warmer climates. Moisture is necessary for infective larvae to ascend the herbage and so transmission by all species is low in the absence of dew, rain or irrigation. Desiccation will kill larvae on the pasture but those still within fecal deposits can survive to emerge when rainfall resumes. Severe outbreaks of disease may occur after the first rains following a prolonged drought. Summer storms during a dry period reduce risk as released larvae quickly die when the pasture dries out. In temperate climates, larvae leaving accumulated dung pats in the autumn after a dry summer may be conditioned for hypobiosis, thereby increasing risk of Type II disease (see 'Outbreaks of disease' below).

**Potential sources of contamination**

on sheep pastures at the start of the grazing season are larvae that have overwintered on the herbage and, most importantly, larvae from eggs more recently shed by ewes during the PPER. On cattle pastures, overwintered larvae are of greatest significance as yearling and adult cattle generally deposit insignificant numbers of trichostrongylid eggs. In both cases, overwintered larvae do not survive long in the warmer spring weather as the food stores on which they depend are soon exhausted. In the meantime, however, some will be ingested by susceptible lambs or calves. Disease does not occur at this stage unless massive numbers of larvae have survived the winter. Most often, these first infections are small and asymptomatic. They are nevertheless of great epidemiological significance as the eggs produced are responsible for the infective larvae that appear on the pasture later in the season.

**The rate of larval development**

is temperature dependent, occurring faster in warmer weather. The lifespan of infective larvae is, however, shorter at higher temperatures as food stores are used more quickly. The number of larvae accumulating on pasture is therefore a balance between these two opposing factors and tends to follow a stereotyped pattern in each locality. Computer models are being developed to investigate these trends in different climatic zones and under different husbandry systems. The general pattern of pasture infectivity may however be temporarily disrupted by short-term weather fluctuations. For example, with *O. ostertagi* in grazing calves in temperate climates, the new wave of infective larvae (the 'autoinfection peak') will not appear before mid-summer, but this event may be delayed or interrupted by periods of dry weather. As larvae of each trichostrongylid species have different optimum developmental conditions, peak numbers will occur at different times. In England, for example, the 'succession of species' in sheep is *N. battus* followed by *O. circumcincta* then *H. contortus* and finally *Trichostrongylus* spp.

**Outbreaks of disease**

due to trichostrongylid infection can occur in different ways. Clinical signs are normally initiated when developing worms emerge from the mucosa of the alimentary tract. With normally developing mucosal larvae, this will happen when the daily intake of infective larvae has risen to a level sufficient to overwhelm any immunity that may have developed. This is sometimes termed 'Type I' disease. The onset of clinical signs will be considerably delayed however when damage is produced by previously hypobiotic larvae resuming their development. This often occurs during the winter housing period and is known as 'Type II' disease. Additionally, hypersensitivity responses to incoming larvae can occur under some circumstances when immune animals graze heavily contaminated pasture. This has been proposed as an explanation for the so-called 'non-parasitic scouring syndrome' in southern Australia, which occurs in pregnant and lactating ewes grazing contaminated pasture.

**Trichostrongylosis in sheep**

is favored by cool, wet weather and is a disease of the winter months in those areas where rainfall occurs chiefly at this time of the year. Although the eggs and larvae of *Trichostrongylus* spp. tolerate cold, they are not resistant to freezing temperatures. Consequently, in very cold climates disease may be more common in the late summer and autumn. In arid areas the disease is of little significance except in unusually wet years. *T. axei* can infect a range of species but is primarily a parasite of cattle and is usually only seen in other hosts when grazing cattle pastures.

**The epidemiology of bovine ostertagiosis** is complex. Type I disease is mostly seen in first-season grazing animals particularly dairy calves heavily stocked on permanent calf paddocks. Large numbers of adult worms are present and egg counts are high. In areas with warm climates, Type I ostertagiosis may be seen in almost any season but is particularly important in winter and spring. In areas with harsher winters, as in northern Europe, larvae overwinter in sufficient numbers to infect autumn-born calves after spring turnout. The resulting small worm burdens produce eggs that give rise to a new generation of infective larvae. These 'autoinfection larvae' are responsible for the disease outbreaks that occur from mid-July to the end of the grazing season. Type I ostertagiosis also occurs in beef cattle if placed on heavily infected pastures immediately after weaning. It is less often seen in calf suckler or extensive management systems because of the relatively low number of susceptible animals per unit area of grazing land.

**When hypobiosis occurs**, many fourth-stage larvae accumulate in the gastric glands. Few if any clinical signs will be apparent and egg counts will be zero or low. This condition is called pre-ostertagiosis and occurs at a definite time each year depending on the region - autumn in northern Europe and spring in Australia. Type II disease occurs when waves of hypobiotic larvae emerge from the parasitized glands some 4–5 months later. This is typically when cattle are 12–24 months of age, although Type II disease is sometimes seen in older animals. Few adult worms will be present and egg counts will be correspondingly low.

**Goats** do not build up an effective immune response against trichostrongylid worms and so remain susceptible to disease throughout their lives. The risk is enhanced if they are forced to graze rather than browse. Problems are frequently encountered on hobby farms where goats are overstocked on small paddocks.

**PATHOGENESIS**

Each trichostrongylid species differs in its habit and in the damage it causes and so details of the corresponding disease processes will vary correspondingly. The major mechanisms leading to diarrhea, weight loss and production deficits can however be described in general terms.

**In abomasal infection** with *Ostertagia* spp., developing larvae distend the gastric glands and produce small white nodules on the mucosal surface, but these are of little clinical significance. More important changes take place
18–21 d after infection when worms start to emerge from the glands. This triggers a hyperplastic reaction in neighboring glands causing larger nodular lesions which, if numerous, may coalesce. Many of the cells lining affected glands are non-functional. The resulting reduction in acid-secreting parietal cells leads to increased gastric pH, which may rise to 6–7. This produces several domino effects. First, incoming bacteria and ruminal protozoa are not killed. Second, pepsinogen is not converted to pepsin as this only happens in an acid environment, thus, no pepsin is available for protein digestion. Accumulating amounts of the precursor molecule are reflected in elevated blood pepsinogen concentrations. Third, blood gastrin rises as the body attempts to stimulate more acid secretion. The hyperplastic mucosal reaction also results in increased permeability of the epithelial sheet. This leads to protein loss into the lumen of the abomasum. In mild uncomplicated cases, this protein leak and the disrupted protein digestion are both compensated by digestive/absorptive intestinal mechanisms. In severe cases, hypoaalbuminemia, tissue edema and weight loss are apparent. Between these extremes, these processes lead to reduced muscle protein synthesis and consequent productivity losses.

Intestinal trichostrongylid infections are associated with inflammatory changes, a thickening of the mucosa and a stunting or flattening of the villi. Epithelial enzyme activity is reduced. *Nematodirus* and *Cooperia* lie in close contact with the mucosa but *Trichostrongylus* spp. larvae and adults form superficial tunnels, causing additional tissue disruption. Lesions are confined to the anterior small intestine and their severity is determined by the density of worms. Surprisingly, malabsorption is not a marked feature of pathogenesis as unaffected parts of the intestine can usually compensate. Consequently, protein digestibility and absorption may be normal. There is, nevertheless, poor retention and utilization of nitrogen due to a protein-losing enteropathy, together with excessive losses from sloughed cells and mucus production. This contributes to production losses and causes hypoalbuminemia and edema in severe cases. Wool growth is affected and the fleece becomes brittle. Mineral absorption is impaired, resulting in reduced skeletal growth, bone density and mineralization. *T. colubriformis* infection reduces the absorption of phosphorus and increases the loss of endogenous phosphorus, thus leading to a phosphorus deficiency. As with abomasal parasitism, the precise reason for the diarrhea associated with these infections is unknown.

**Reduced productivity** in both abomasal and intestinal parasitism is mostly due to a reduction in appetite that is a constant feature of these infections. In one field study, untreated heifers spent on average 105 min less per day grazing as compared with a matched treated group and their daily herbage intake was 0.78 kg dry matter per day lower. Experimental studies show that inappetence accounts for over 60% of the difference in weight gains between *Ostertagia*-infected and worm-free sheep and cattle. The associated mobilization of adipose tissue gives rise to increased non-esterified fatty acid levels. Voluntary feed intake may be significantly depressed even in parasitized animals showing no clinical signs. The elevated gastrin levels in abomasal trichostrongylid infections impair reticulo-ruminal motility and slow abomasal emptying, leading to a stasis of ingesta and hence a reduction in feed intake. Other, as yet unknown, mechanisms must also be involved as gastrin levels are not affected by intestinal worms, yet these also depress appetite.

**CLINICAL FINDINGS**

In sheep the two most susceptible age groups are weaner lambs and yearlings. Those over 18 months of age are less prone because of immunity gained from previous infestation. The onset of disease is generally insidious with young animals initially failing to grow satisfactorily and later becoming unthrifty, and lacking in vitality and bloom. If they are observed sufficiently closely their food intake can be seen to be reduced. This may be the full clinical picture in many flocks which are considered to have ‘weaner illthrift’. More severely affected sheep pass dark green, almost black, soft feces which foul the wool of the breed. Lamb and yearling flocks are most seriously affected and a constant mortality begins, a few animals dying each day. The losses are not acute but may eventually exceed 35%. A more dramatic picture occurs when young lambs, especially those in the 6 to 12-week age group, are exposed to sudden pasture challenge with *Nematodirus* spp. There is profuse watery diarrhea and the lambs quickly become dehydrated. Mortality can be high and deaths may start within 2 d of the first observed illness.

**In cattle**, calves are most vulnerable in their first grazing season, although yearlings and, less often, adults are sometimes affected. They:
- Lose weight rapidly
- Pass soft feces which eventually become very thin and dark green to yellow in color
- Develop a long, dry hair coat
- Become dehydrated with sinking of the eyes in the terminal stages.

Until the last they continue to eat, although the amount of food taken is much below normal. Gross anemia is not evident but the mucosa are pale and dry. Submandibular edema is common, especially in Type II disease. The temperature may be elevated (39.5°C; 103°F) and the heart rate increased (120 bpm) in calves showing dehydration. In the terminal stages the calves become weak and emaciated. Type I ostertagiosis in calves is characterized by high morbidity and low mortality. Although morbidity is low in Type II disease, clinical signs are generally more severe and the prognosis poorer.

**CLINICAL PATHOLOGY**

Fecal egg counts have to be interpreted with caution as they are only well correlated with worm burdens in young animals. Egg counts are however often over 1000 epg (eggs per gram feces) in Type I ostertagiosis. Zero or low epg values may be recorded if:
- The worm burden comprises mainly immature stages (as in Type II disease or some outbreaks of nematodiosis)
- Intestinal damage persists after the worm population has been expelled by immunity or anthelmintic treatment
- Disease is associated with hypersensitivity to incoming larvae.

Different trichostrongylid eggs, other than *Nematodirus*, cannot easily be differentiated and cultures must be made if species determination is necessary.

**Plasma pepsinogen** estimations are performed routinely in many laboratories as an aid in the diagnosis of ostertagiosis. Elevated values also occur in hemochromas. The test is difficult to standardize so results from different laboratories cannot be compared but, in calves, levels higher than 3000 iu tyrosine are generally considered to indicate a pathogenic worm burden. Pepsinogen levels decline after effective anthelmintic treatment but do not return to pre-infection values. Older immune cattle may show elevated values when grazing contaminated pasture, even though few incoming larvae are able to establish. Plasma gastrin concentrations reflect the size of the abomasal worm burden in both young and older animals, but currently can only be measured by radioimmunoassay, which limits their field application. Gastrin occurs in several molecular forms and, consequently, test kits have to be validated before use with bovine blood as not all are suitable for this purpose.
**Moderate anemia** often occurs with hemoglobin levels around 6–8 mg/dL and is more evident in *Cooperia* and *Ostertagia* spp. infections than in trichostrongylosis where there may be polycythemia. Serum protein concentrations may be as low as 4–5 mg/dL with a marked reduction in serum albumin values.

**Species-specific enzyme-linked immunosorbent assay (ELISA) tests** are being developed for use with samples from bulk milk tanks but are currently only available for epidemiological research.¹⁹

**NECROPSY FINDINGS**

Adult worms are found in the abomasum or small intestine depending on the predilection site of the individual species. A total worm count is the critical measure of the degree of infestation. Counts less than 2000 in mixed species of sheep are considered to be light, while counts over 10 000 are heavy, but massive counts of 50 000 and more are often seen. In cattle, burdens of 40 000 and above are seen in Type I ostertagiosis outbreaks (the majority are adults), while in Type II disease worm numbers may be 100 000–200 000, with occasional animals harboring a million or more. In these cases about 90% are in the fourth larval stage. Trichostrongylids are small, translucent and threadlike so even adults can easily evade detection by the naked eye at necropsy. Worm counting therefore involves washing the mucosa, sieving the washings and lumenal contents, re-suspending the residue, taking aliquots and picking out and identifying the nematodes. A more rapid but effective field technique for demonstrating intestinal worms is to:

- Roll a loop of duodenum inside out over a test tube or glass rod
- Immerse this first in aqueous iodine solution (iodine 30 g, potassium iodide 40 g, water 100 mL) for several minutes
- Immerse in a 5% solution of sodium thiosulfate for a few seconds.

The mucosa is decolorized but the brown-stained worms retain their color and are easily seen.²⁰ Mucosal larval stages have to be released by digesting the tissues with acid-pepsin.

**Gross pathological findings** are often not striking, apart from the non-specific lesions of emaciation, dehydration, moderate anaemia and evidence of scouring. In severe cases, the mucosa of the abomasum and upper small intestine may be hyperemic and swollen, and local lymph nodes enlarged. In ostertagiosis there will be numerous raised nodules which may be discrete or confluent forming a ‘morocco-leather’ appearance.

Abomasal folds are edematous and diphtheritic may sometimes be apparent. A putrid smell may reflect the growth of microorganisms in the ingesta and estimation of the pH will confirm loss of acidity.

Heavy *T. axei* infection in lambs, calves, and horses causes circumscribed raised plaque-like hyperplastic lesions on the abomasal mucosa, sometimes with an eroded center. Close inspection is needed to see the villous atrophy associated with intestinal *Trichostrongylus* species. Initially this is diffuse but later appears as discrete patches ('fingerprint lesions').

**DIAGNOSTIC CONFIRMATION**

PGE should not be diagnosed on the basis of a fecal egg count alone. In sheep, a total worm count should be performed whenever possible, preferably with a peptic digest of the mucosa. The results should be considered together with the:

- Clinical signs
- Age of the animal
- Season of the year
- Nutritional status
- Grazing history.

The critical test in an outbreak of disease is the response to treatment. Because the epidemiology of the various species differ, it is important that the main contributing species be determined so that adequate control measures can be taken. In calves, clinical diagnosis can be confirmed by plasma pepsinogen estimation, but this assay is less helpful in adult cattle.

**DIFFERENTIAL DIAGNOSIS**

PGE has to be differentiated from other common causes of emaciation and diarrhea in groups of young animals such as:

- Malnutrition
- Copper deficiency (in cattle)
- Coccidiosis (in particular, *Nematodirus* and coccidiosis occur in lambs of the same age)
- Johne's disease
- Chronic fasciolosis.

**TREATMENT**

Many broad-spectrum anthelmintics are now available that combine high efficiency against larval and adult worms with low toxicity in sheep and cattle. Most however belong to just three major chemical groups:

1. **Avermectins/milbemycins**, also known as the macrocyclic lactone anthelmintics (MLs), which interfere with nerve transmission by opening chloride channels
2. **Benzimidazoles (BZDs)**/probenzimidazoles, which bind to tubulin and disrupt nutrient uptake
3. **Imidazothiazoles/tetraphydropirimidines**, which act as cholinergic agonists

**Dosage rates and label claims** may vary with formulation and from country to country according to local conditions and regulatory requirements. Figures given in this chapter should therefore be regarded only as a general guide.

**Cattle**

In cattle, ivermectin, doramectin, and moxidectin are given at 0.2 mg/kg by injection or 0.5 mg/kg as a pour-on formulation. Eprinomectin pour-on 0.5 mg/kg is the compound of choice for adult dairy cattle as it has a nil milk withdrawal period.²¹ Albendazole 7.5 mg/kg, febantel 7.5 mg/kg, fenbendazole 7.5 mg/kg, netobimectin 7.5 mg/kg, and oxendazole 4.5 mg/kg are given orally. Levamisole can be used orally or by injection at 7.5 mg/kg or as a pour-on at 10 mg/kg.

Sustained release intraruminal devices (‘boluses’) for use in cattle provide extended periods of protection. For example, fenbendazole is released for up to 140 d from one bolus, while a biodegradable bolus releases morantel tartrate for at least 90 d. There are also pulse-release boluses containing oxendazole, which release five or six anthelmintic doses at 3-week intervals.

**Sheep**

In sheep, the dose rate for ivermectin, doramectin, and moxidectin (which are given orally or parenterally) is 0.2 mg/kg. Dose rates for the BZDs (given orally) are: albendazole 5 mg/kg, febantel 5 mg/kg, fenbendazole 5 mg/kg, netobimectin 7.5 mg/kg, mebendazole 15 mg/kg, and oxendazole 5 mg/kg. Levamisole can be used orally and parenterally at 7.5 mg/kg. Morantel citrate monohydrate is also used as a drench in sheep. Pour-on formulations are not used in sheep as the wool grease does not allow absorption through the skin. Intraruminal devices for use in sheep have been developed which release albendazole or ivermectin over 100 d.²²,²³

**Goats**

Goats metabolize some anthelmintics more rapidly than do sheep and elevated dose rates are sometimes required to obtain a satisfactory level of control. Even then, there may be more surviving worms and consequently anthelmintic resistance tends to develop much more quickly in goats than sheep. Examples of special dose-rates for goats include: albendazole 10 mg/kg and levamisole (which should
be used with caution in goats) 12 mg/kg. Ivermectin can be given at the normal dose-rate of 0.2 mg/kg.

**CHOICE OF ANTHELMINTIC**

The choice of anthelmintic depends on a number of considerations. Anthelmintic resistance is a real or emerging problem in many sheep-rearing areas. Side resistance occurs within chemical groups and multiple-resistant strains have been reported. This can impose a severe constraint on product choice. Other factors include:

- **Price**
- **Safety (including meat and milk residues and effect on environment)**
- **Ease of administration**
- **Spectrum of activity.**

Older products were most active against adult worms, but many now have activity against larval stages. Fewer however have consistently high efficacy against hypobiotic larvae and care is needed in selecting a suitable product to treat or prevent Type II disease. Products with claims for this purpose at standard dose-rates include avermectins/ milbemycins, albendazole, fenbendazole, oxfendazole, and thiophanate, while netobimin is active at an elevated dose-rate (20 mg/kg). The benzimidazoles are ovicidal, which may be beneficial if stock are moved to a new pasture after treatment. Animals with PGE may also be harboring other parasites The avermectins/ milbemycins have a very broad spectrum of activity including some ectoparasites but are inactive against cestodes and trematodes. Some broad-spectrum BZDs are effective against cestodes and one, albendazole, is also active against mature *Fasciola hepatica*. The avermectins/ milbemycins are excerted in the feces and may affect insects colonizing the dung pat. The environmental impact of this has probably been overstated as only a small proportion of the fecal mass on a property will contain anthelmintic, allowing adequate refugia for maintenance of insect populations. This class of compound should however be used with caution if there is concern that beneficial insects may be vulnerable, for example, dung-beetles in some arid zones.

**Novel methods for increasing drug availability** and anthelmintic effect within the body are under investigation and should be adopted by veterinarians as they become available. There is uncertainty when, or even if, new chemical classes will become commercially available for nematode control and so it is essential that existing products are used as efficiently as possible to extend their effective life. Using measures which maximize the potency of anthelmintics can slow the onset of resistance and increase efficacy against partially resistant strains. The efficacy of the BZDs and orally administered avermectins depends on their residence time in the rumen and some simple measures can be taken to increase this. Correct drenching procedure (gun tip over tongue and drench dispensed directly into esophagus) will avoid stimulation of the esophageal groove reflex and ensure that the dose does not bypass the rumen. As there is an inverse relationship between feed intake and rumenal residency time, a reduction in feed intake (e.g., by penning) for 24 h before prophylactic drenching retards transit time and significantly enhances the activity of BZDs and ivermectin. With BZDs, drug residency time in the rumen can be further increased and efficacy enhanced by dividing the dose and giving it at 12- or 24-hour intervals. This principle is reflected in medicated lick-blocks and intramuscular boluses which provide daily low-level BZD doses.

**Continued protection** must be given to animals after treatment for clinical PGE. Irrespective of the drug used, treated animals should be moved to a clean paddock (i.e., one not contaminated with large numbers of infected larvae) which provides an adequate plane of nutrition. The ovicidal action of the BZDs is particularly useful if animals are being placed on very clean areas such as cereal stubble. However, it is probably of lesser importance on many farms where residual pasture contamination is always present. If clean pasture is not available, protection can be provided by use of an anthelmintic with persistent activity against incoming larvae. In cattle, ivermectin provides up to 21 days' protection against *O. ostertagi* and up to 14 days' against *Cooperia* spp. Corresponding figures for eprinomectin are: 28 and 21 d; for doramectin: 35 and 21 d (by injection) and 35 and 28 d (pour-on); and for moxidectin: up to 28 days against *O. ostertagi*. The persistent anthelmintic effect of avermectins in sheep is much shorter and there is probably little useful effect against intestinal trichostrongylids.

Moxidectin given by injection has a label claim for 5 weeks protection against *O. circumcincta* and 2 weeks against *T. colubriformis*.

**CONTROL**

Control measures are aimed at reducing pasture contamination in order to minimize the uptake of infective larvae, thereby preventing disease and allowing optimal productivity. The cost of any program and treatments must accord with potential economic benefits. Where individual animals are valuable, labor-intensive strategies may be justified. Many husbandry systems however will support only low input solutions and treatments may only be feasible when animals are handled for other management procedures. Epidemiological patterns differ for each worm species and vary considerably from region to region, with subtle variations often occurring from locality to locality. It is therefore beyond the scope of this text to make specific recommendations for control but it is possible to describe general principles which can be adapted to local needs.

Knowledge of local epidemiology is a necessary prerequisite for designing a control program. In particular, the animals providing the major source of contamination should be identified, the period of development from egg to infective larvae and the availability of infective larvae throughout the year known. It is essential to formulate clear and precise control objectives, otherwise much time and expense can be wasted. Management may have to be adjusted to aid control. On organic farms, where anthelmintic usage is greatly restricted, worm control may be a major factor in determining stocking density and grazing management. Often, control measures are aimed primarily at protecting the most susceptible group, that is, young animals up to 18 months of age exposed to infestation for the first time.

**Anthelmintic resistance** is an important consideration influencing the choice and intensity of control measures. Even if economically justified, frequent routine treatments impose strong selection pressure on worm populations and encourage the development of resistant strains. As only three major chemical groups are currently available for the treatment of gastrointestinal and pulmonary nematodes, it is imperative that their usefulness is conserved for as long as possible. Many anecdotal field reports of resistance are erroneous, the problem being one of reinfection or incorrect anthelmintic usage. Nevertheless, resistant and multi-resistant strains are already prevalent in many sheep-rearing areas. So far, there have been few reports from cattle. The following recommendations have been made to slow the onset of resistance:

1. Use an effective drug in the most efficient manner:
   - Check fecal egg counts regularly to confirm that chosen products remain effective
   - If a worm population is already partly resistant to a compound, continued use of products based on that chemical group will endanger the health of the animals and reinforce the resistance.
2. Do not underdose (this may encourage resistance):
   - Weigh each animal or the heaviest individuals in a group
   - Comply with all label recommendations
   - Ensure good maintenance and calibration of dosing equipment.
3. Use the minimum number of doses needed to maintain health:
   - Strike a balance between encouraging resistance by treating too intensively and allowing pasture contamination to rise to unacceptable levels.
4. Use sound epidemiological principles:
   - Utilize an integrated approach to worm control which maximizes the potential of management techniques and minimizes reliance on anthelmintics.
5. Rotate the chemical group annually (to ensure that worms are exposed to compounds with a different mode of action each year):  
   - Remember there is no benefit in rotating compounds within a chemical group, nor in using a group already rendered ineffective by anthelmintic resistance.
6. Avoid introducing resistant worms onto a property (obvious, but often overlooked):
   - Place all new stock into quarantine and treat with an effective compound
   - Do not graze goats on sheep pastures (as caprine worm populations often have a higher prevalence of resistance genes).
7. Make sure that the farmer is aware of the problem and the consequences of anthelmintic resistance.

The concept of maintaining parasite refugia is assuming greater prominence as a means of conserving anthelmintic efficacy in modern control strategies. The theoretical background and clinical application are discussed in detail in Abbott et al. (2004) – see Review Literature below. Worms ‘in refugia’ are those not exposed to anthelmintic when the flock is treated. They thereby escape selection pressure for resistance. When the flock subsequently becomes re-infected, the genetic material from parasites surviving treatment will be diluted by susceptibility genes from worms ‘in refugia’ at that time. This slows the rate at which resistance develops and extends the period over which the drug maintains clinical efficacy on the farm. The refugia concept is best illustrated by an example. In cooler temperate climates, infective Ostertagia larvae overwinter on grass in large numbers but most Haemonchus larvae succumb to the cold. If ewes are dosed during the winter to eliminate the periparturient egg-rise, only a small proportion of the Ostertagia population (those in the animal) are exposed to the anthelmintic, while the remainder (those on the pasture) are ‘in refugia’. In contrast, a high proportion of the total Haemonchus population is exposed to the drug (as there are few larvae ‘in refugia’ on the pasture) and in consequence there is an enhanced risk of anthelmintic resistance developing. From this viewpoint, therefore, it could be beneficial in the longer term to withhold the winter treatment from some ewes. This would ensure that the majority of eggs subsequently dropped onto the pasture are produced by susceptible worms. Similarly, dose and move systems encourage resistance as all eggs dropped onto the new pasture are from worms that have survived treatment. It could therefore be advantageous to use a short-acting drug and to delay the move. This would ensure that the animals acquire a small burden of susceptible worms before the move. These strategies involve obvious inherent risks and all aspects of a particular situation must be carefully considered before implementation.

Protocols for detecting anthelmintic resistance in a herd or flock are available. The fecal egg-count reduction test can be performed easily without sophisticated equipment. The egg value should be reduced by 95% or more, but false negatives may be obtained with BZDs (if female worms are sterilized but not killed) and false positives with levamisole (if large numbers of mucosal larvae present at the time of dosing survive treatment). Laboratory tests include egg-hatch assays for BZDs and larval development tests for avermectins and levamisole. Improved assays, including polymerase chain reaction (PCR)-based tests for BZDs, are being developed.

The Principles of Control generally fall into three categories:

1. Preventive
2. Evasive
3. Diluting.

Preventive measures are those that place livestock on clean pasture or that use early season chemoprophylaxis to ensure clean grazing later in the season.

Evasive strategies are those in which pasture contamination is allowed to build up naturally but susceptible stock are moved on to clean grazing before pathogenic numbers of infective larvae have accumulated. An anthelmintic dose can be given at the time of the move. This ‘dose and move’ system is effective and reduces anthelmintic dosage very considerably. It may however encourage resistance as discussed in the previous paragraph.

Diluting systems reduce the effective stocking density of susceptible animals by grazing them alongside non-susceptibles (older immune stock or alternative species). In cow-calf systems, for example, adults produce at least four times as many feces as their calves but their average egg count is typically no more than 15 epg. The number of trichostrongylid eggs and the subsequent accumulation of infective larvae on the herbage will therefore be considerably smaller than if the pasture was fully utilized by calves alone.

In cool temperate regions, control measures can take advantage of the fact that overwintered larvae die away in early summer. Hay or silage pastures therefore provide safe grazing after the grass has been cropped. Alternatively, suppressive anthelmintic therapy over the first 90–100 d of the grazing season will prevent overwintered larvae establishing in the host and thereby stop the subsequent accumulation of infective larvae on the herbage. This strategy is very effective on set-stocked permanent calf paddocks provided that no untreated animals are introduced. The required effect can be obtained by use of an intraruminal anthelmintic device administered around the time of spring turnout or by giving two or more doses of an anthelmintic with prolonged activity against incoming larvae. As the object is to prevent egg excretion, the required treatment interval is calculated by adding the length of the protective effect (which varies with the product) and the prepatent period of the worms (about 3 weeks). Ivermectin given 3, 8, and 13 weeks after turnout and doramectin given at turnout and 8 weeks later are very effective for this purpose, as are the intraruminal boluses listed earlier.

Controlled field studies have demonstrated significant weight-gain advantages from this approach but, as with cattle lungworm, there is concern that the level of immunity acquired during the first grazing season may be reduced. Usually this is of no clinical consequence but results from an epidemiological survey of 87 farms in Holland suggest a beneficial relationship between immunity to nematodes gained during the first grazing season and the growth rate of cattle during their second grazing season. It seems that optimal protection has to balance risk of production losses in first and subsequent grazing seasons but there is currently no objective way of doing this. One suggestion is that rumen boluses would...
be better employed if used to provide anthelmintic cover in the second half of the grazing season when pasture contamination is high ("metaphaxis"). Good immunity would be assured but the growth rate advantage may be inferior to that obtained with the early season prophylaxis described earlier.34 If cattle have been exposed to high pasture challenge in the autumn, they should be dosed with a product active against hypobiotic larvae at housing or during the winter to prevent Type II ostertagiosis. In countries where Dictyocaulus viviparus is a problem, control of PGE and lungworm must be integrated.

Elimination of the periparturient egg rise is the most important feature of worm control in sheep. Ideally, ewes should be dosed towards the end of gestation and again 1 month after parturition with a product active against hypobiotic larvae. Lambs should be dosed at weaning and if possible moved to clean pasture. In most cases, further treatments will be necessary to maintain health until marketing but these should be kept to a minimum. The number will depend on the stocking density, initial pasture contamination and weather. A compromise has to be struck between an acceptable level of disease control and the risk of inducing anthelmintic resistance. Fecal egg counts can be used to check the adequacy of the dosing interval and the efficacy of the treatments.

Control of Nematodirus differs from that of other forms of PGE because the ewe is not a source of contamination. The simplest form of control is to avoid putting the new lamb crop onto pasture contaminated by the previous year’s lambs. Often however this is not feasible and prophylactic anthelmintic doses at 3-week intervals are necessary to cover the limited period of risk (May to early June, for example, in Scotland). Waiting for the first clinical signs before starting treatments is not recommended as deaths can occur very quickly. The precise timing of the egg hatch varies from year to year according to prevailing weather conditions, but forecasting systems are in operation in some countries.

In warm temperate regions, PGE control strategies are more difficult to design as animals graze all year round. The main transmission period is late winter and early spring. Treatment of beef cattle at weaning and once or twice at locally determined intervals thereafter is often sufficient to reduce pasture contamination.35 In sheep, an effective program is to dose lambs at weaning and move them onto safe pasture. Two or three subsequent treatments at 8-week intervals may be needed. In summer rain-fall areas, Haemonchus is an additional hazard and systems have to be designed to combat this as well as other gastrointestinal worms.

In regions with a prolonged dry season, larvae will be killed on the ground and, providing there are no foci of infection around water holes etc., a single strategic anthelmintic dose at this time with a product active against hypobiotic larvae may be more effective at maintaining low pasture contamination around the year than repeated dosing throughout the wet season. This single dose may, however, apply greater selection pressure for resistance, since the whole parasite population is exposed to the drug and survivors are likely to carry resistance genes.

Reduced reliance on anthelmintics can be achieved in a number of ways. For example, alternate grazing with sheep and cattle can be employed to good effect. In Australia, the number of anthelmintic drenches can be substantially reduced by alternation at 2–6 month intervals.30 In northern Britain annual stock rotations, sometimes with an arable crop grown in the third year, can be employed to good effect. In autumn, they should be dosed with a product active against hypobiotic larvae and prophylactic anthelmintic doses at weaning and if possible moved to clean pasture. In most cases, further treatments are not recommended as deaths can occur very quickly. The precise timing of the egg hatch varies from year to year according to prevailing weather conditions.35 Feed supplementation to enhance host resilience and resistance to infection, vaccination and future prospects for breeding lines of sheep with innate host resistance are described under Haemonchus.

Breakdowns in control programs are usually due to:

- Failure to prevent worm egg-output at times critical to the accumulation of infective larvae on the pasture.
- Failure, after treatment, to move animals on an already contaminated pasture to a clean environment.
- Use of an insufficient dose or incorrect anthelmintic.
- Failure to repeat treatment or repeating treatment at overlapping intervals at times of high risk.
- Failure to appreciate that not all anthelmintics kill all immature stages, particularly hypobiotic forms.
- Introduction of susceptible sheep from a worm-free environment into a high risk area.

- Failure to protect young animals adequately.

**REFERENCES**

**Hemorrhagic in ruminants**

**ETOLOGY**

Sheep, cattle, and goats are all affected by species of the nematode genus Haemonchus, which is closely related to the other trichostrongylid species of ruminants.
**Hemonchosis in ruminants**

**Etiology**

The nematode parasite *Haemonchus contortus* in sheep and goats and *H. placei* in cattle.

**Epidemiology**

Female worms produce large numbers of eggs, infective larvae develop rapidly in warm wet conditions; dangerous levels of pasture contamination can therefore accumulate rapidly.

**Signs**

Acute: sudden death, anemia;

Chronic: wasting, anemia, anasarca.

**Clinical pathology**

Anemia, hypoproteinemia; often high fecal egg count.

**Lesions**

Anemic carcasses; abomasal mucosa hyperemic with many red-colored worms.

**Diagnostic confirmation**

'Barber's pole' appearance of female worms (if fresh).

**Treatment**

All modern broad-spectrum anthelmintics; also, closantel, rafaxide, nitroxynil, disophenol and some organophosphates; care needed in selection as resistant and multiresistant strains of *H. contortus* occur.

**Control**

Strategic dosing schemes using broad-spectrum anthelmintics; closantel or disophenol can be used to reduce dependence on broad-spectrum products.

**EPIDEMIOLOGY**

The epidemiology of hemonchosis is largely determined by the high fecundity of the female worms and the speed with which infective larvae can develop in warm, humid conditions. Thus, when conditions are favorable, large numbers of infective larvae can accumulate very rapidly on pasture. Opportunities for transmission are however restricted by the susceptibility of the larvae to desiccation and cold.

**Hemonchosis is an important disease** of sheep, goats, and cattle in all but the coldest regions. The greatest economic impact is seen in sheep in tropical and warmer temperate countries, especially where there is good summer rainfall. It is not uncommon for serious outbreaks to occur in cooler climates during periods of high humidity in summer.

The disease is uncommon in semi-arid regions unless there are opportunities for transmission to occur in, for example, irrigation schemes. In sheep, losses occur mostly in lambs, especially those recently weaned, but yearlings and mature sheep may also be affected. Goats of any age are susceptible but their browsing habit may protect them from the heaviest sources of contamination. Dairy calves are the most commonly involved group amongst cattle but steers and other young cattle up to 3 years of age may also be affected.

**Predisposing causes** for hemonchosis include overcrowding, lush pasture, hot and humid climatic conditions and a low plane of nutrition. Disease can be precipitated in several ways. An important causal mechanism in sheep is when lambs, that may be in excellent condition on good grazing, are overcome by a sudden massive wave of pasture contamination. Sheep in poor condition may be clinically affected by worm burdens too small to harm an otherwise healthy animal. Outbreaks of disease may occur in sheep overwintered indoors if large numbers of hypobiotic larvae mature simultaneously. 

Cattle harboring subclinical infestations while on a good plane of nutrition may show clinical signs if the pasture subsequently fails because of drought or overgrazing. In goats, *Trypanosoma congolense* infection has been shown to increase the susceptibility to *H. contortus*.

The climatological conditions that permit the development of hemonchosis in sheep have been the subject of much research. Bioclimatographs have been produced for many different geographic areas. In regions with narrow diurnal temperature fluctuations, outbreaks are likely during months with a mean maximum temperature of 18°C (64°F) and more than 5.25 cm rain. In areas with regular summer rainfall, larval availability increases from late spring to reach maximum levels by late summer to early autumn and quickly declines in winter. A similar trend, but with fluctuating larval numbers, occurs in areas with more variable rainfall patterns.

**The self-cure phenomenon** is a sudden naturally occurring expulsion of adult *H. contortus* which may also, although not invariably, eliminate incoming larvae. In some areas, this may be associated with changes in the pasture but more often it occurs in sheep when a large uptake of infective larvae is superimposed on an established worm burden in a sensitized animal. Self-cure may also expel existing *Ostertagia circumcincta* and *Trichostrongylus axei* from the abomasum and *Trichostrongylus spp.* from the small intestine. Strain or breed differences occur and a genetic resistance operating primarily against worm establishment and probably controlled by the immune response has been reported. There is no complete self-cure with *H. placei* in calves but after an initial infection there is a rapid decline in egg laying, adults are expelled and subsequent larval development is retarded. Immunity is much stronger in calves than in sheep.

**PATHOGENESIS**

Vigorous bloodsucking by both fourth-stage larvae and adults is the main factor differentiating the pathogenesis.
of *H. contortus* from that of other abomasal nematodes. The histological changes and biochemical sequelae associated with *Ostertagia* infections also occur in hemonchosis but in addition a hemorrhagic anemia evolves due to the daily loss of around 0.05 mL of whole blood per worm. The course of the disease depends on the numbers of worms present and the ability of the animal to compensate for acute or chronic losses of plasma proteins, hemoglobin and other blood constituents. In continuing infections, the increased rate of red cell production is maintained at the expense of the animals’ iron stores and a state of iron deficiency occurs. Death may be acute and result purely from blood loss or may be more gradual and accompanied by weight loss, anemia, and hypoproteinemia. Poor growth in young lambs can result from a reduction in their ewes’ milk production. Susceptibility to hemonchosis varies with breed. Those with superior resistance include the Scottish Blackface, Red Maasai, Florida Native, St Croix, and Barbados Blackbelly, whereas the Hampshire Down is relatively susceptible. Individuals within a flock also vary in vulnerability. This natural resistance to infection is heritable.

**The role of nutrition** in modifying the pathogenesis of hemonchosis in lambs is undergoing intense investigation. There is experimental evidence that lambs on a high protein diet are better able to withstand *H. contortus* infestation. There are considerable breed differences; in some cases, animals with a higher protein intake mount a more effective immune response, in others they are better able to tolerate and compensate for the blood losses associated with the infection.

**CLINICAL FINDINGS**

Hemonchosis causes heavy losses due to animal deaths and reduced production. Lambs and young sheep are commonly affected by the acute form of the disease. Often only a few individuals will be seriously affected but in very severe outbreaks, a large proportion of the flock may suffer if not treated. Animals may be found dead without premonitory signs having been observed. The mucosae and conjunctivae of such sheep are always extremely pale. More chronic cases show lethargy and muscular weakness, pallor of the mucosae and conjunctivae, and anasarca, particularly under the lower jaw and to a lesser extent along the ventral abdomen. Affected sheep are often noticed for the first time when the flock is being driven: they lag behind, breathe faster, have a staggering gait and often go down. Some sheep may die as a result of exercise but most can rise and walk a little further after rest. Grazing animals lie down a good deal of the time, often around the water troughs; the energy needed to walk and eat appears to be lacking. Most affected sheep show constipation rather than diarrhea. There is a loss of body weight and a detrimental effect on wool growth and quality. In sheep with the chronic condition, there may be extreme weight loss during the dry season, even though larval uptake is negligible at this time. Sheep not fatally affected develop a break in the wool and the fleece may be lost at a later date.

In calves, the disease is characterized clinically by severe anemia and anasarca. Heavy infestations occurring in summer may not manifest clinically until winter when the plane of nutrition declines.

**CLINICAL PATHOLOGY**

As *Haemonchus* is a prolific egg layer, fecal egg counts tend to be high (10 000 epg in severe cases), but it must be remembered that low egg counts may be encountered in the early part of the evolution of the disease when the bulk of the pathogenic worms are in the larval stage. There is a significant rise of abomasal pH soon after infection accompanied by increased plasma pepsinogen and gastrin concentrations. *Worm counts and hemoglobin levels are correlated.*

**NECROPSY FINDINGS**

Gross necropsy findings include severe anemia, gelatinization of fat deposits, general anasarca and the presence of large numbers of readily visible *H. contortus* or *H. placei* in the abomasum. If the cadaver is fresh, the worms may still be attached or swimming actively in the ingesta, but a careful search may be necessary if the animal has been dead for some time. The abomasal wall is hyperemic and blood clots may be present in the mucosa. Small ulcerations may be present where adult worms have been attached. The abomasal contents usually have a distinct brownish color due to the presence of free blood.

**DIAGNOSTIC CONFIRMATION**

In mixed infections, eggs of *Haemonchus* spp cannot be easily differentiated from those of many other gastrointestinal nematodes. Identification and quantification therefore depend on counting larvae in fecal cultures, a procedure not readily applicable in routine diagnosis. The number of worms required to depress hemoglobin levels varies with the weight of the sheep. In Merino sheep up to 20 kg, a hemoglobin level of 10.5 g/dL has been associated with 112 worms and 8.0 g/dL with 355 worms. However, in sheep over 50 kg, 355 and 1259 worms were required to give similar values. At necropsy, counts of 3000 *H. contortus* in lambs and 9000 in adult sheep are usually associated with heavy mortalities.

**DIFFERENTIAL DIAGNOSIS**

**Sheep**

Other causes of sudden death, such as lightning strike, snakebite, anthrax or enterotoxemia are often suggested by the farmer and can only be differentiated by necropsy. The other common causes of anemia include:

- Fasciolosis
- Eperythrozoonosis
- Nutritional deficiencies of copper and cobalt
- Diarrhea is a much more prominent sign in other parasitic infestations, particularly trichostrongylosis and coccidiosis.

**Calves**

Hemorrhagic has to be differentiated from:

- Babesiosis
- Anaplasmosis
- Coccidiosis
- Hookworm infection
- Other causes of anemia including heavy infestations with sucking lice, hemolytic anemia caused by drinking large quantities of cold water, the ingestion of rape, kale, and chou moellier, bacillary hemoglobinuria and leptospirosis.

**TREATMENT**

All the broad-spectrum ruminant anthelmintics are effective against *Haemonchus* provided that resistance has not developed to that chemical group. Ivermectin given by injection provides up to 14 days' protection against re-infection with *H. placei* in cattle and up to 10 days' protection with *H. contortus* in sheep. Moxidectin, by mouth or by injection, gives up to 35 days' persistent activity against *H. contortus*. Some compounds active against *Fasciola hepatica* that bind to plasma proteins are also active against blood-sucking nematodes such as *Haemonchus* and are useful for use where resistance to broad-spectrum products is a problem. These include closantel, rafonamide and nitroxynil. Closantel and disophenol, another narrow-spectrum product, exert a persistent protective effect in sheep for up to 4 weeks. With closantel, this period can be extended by reducing feed intake for 24 h before treatment to enhance the uptake of the drug. Organophosphate anthelmintics are available in some localities for use against resistant strains. *H. contortus* strains resistant to benzimidazoles (BZDs), levamisole, morantel, naphthalphos, ivermectin, moxidectin, and closantel have been reported and strains with...
multiple resistance to two or more of these chemicals are common in some areas. To date, resistance problems have not been reported with *H. placei*.

**CONTROL**

In sheep flocks, a late winter treatment will remove hypobiotic larvae before they resume development and start to shed eggs onto the pasture. Where winters are severe enough to kill most of the free-living stages, this single drench will considerably reduce subsequent pasture contamination but may also expose the parasite population to a high level of selection pressure, thereby encouraging the onset of resistance. In areas where larvae overwinter on pasture and infest lambs in early spring, further treatments may be needed in spring and early summer to prevent an accumulation of infection in the sheep and a subsequent build-up of pasture contamination.

If no routine control is practised and pasture contamination becomes high, stock should be dosed and moved to clean grazing areas. If this is not possible, anthelmintic cover must be provided by using a sustained acting compound such as closantel, disophenol, or moxidectin. Sustained release intraruminal devices for sheep containing ivermectin or albendazole are used in some countries.

In cattle, protection can be given by avermectin/milbemycin treatment or an intraruminal bolus. If none of these are available or economically justified, other broad-spectrum compounds can be given at 2 to 4-week intervals throughout the risk period.

In the wet tropics, a rotational grazing system has been devised based on the observation that infective *H. contortus* larvae are relatively short lived at high ambient temperatures. Small ruminants are grazed sequentially for up to 4 d on a series of suitably sized small plots, each of which is rested for at least 30 d before re-use. Where fencing is not feasible, a similar rotation can be planned on a tethering system. This approach is not effective in temperate areas however as under these conditions infective larvae have a prolonged lifespan and substantial numbers will still be present when the grass needs to be re-grazed.

Frequent treatments with broad-spectrum anthelmintics can lead to the development of anthelmintic resistance. Control programs have therefore been devised which reduce dependence on broad-spectrum products by utilizing the sustained action of closantel against *H. contortus*. Treatment with closantel in late winter kills hypobiotic larvae and, subsequently, overwintering larvae from the pasture as they are ingested. In the case of ewes which lamb in early spring, further treatments in late spring and late summer can provide excellent cover. As closantel has no effect against *O. circumcincta* or *Trichostrongylus* spp., strategic treatments with a broad-spectrum compound must also be incorporated into the scheme. Lambs can be treated with closantel and a broad-spectrum compound when they are about 12 weeks of age and again 12 weeks later. This procedure has been designated the ‘Wormkill’ program and variations on the theme, tailor made for particular localities and management systems, have been widely accepted in parts of Australia where BZD-resistant strains of *H. contortus* are prevalent.

Use over a number of years has reduced *H. contortus* to negligible levels on many farms, but closantel resistance is starting to emerge. Disophenol has been used for a similar purpose in other areas.

A BZD-resistant *H. contortus* population on a farm is unlikely to revert to susceptibility even if this class of compound is withheld from use for a protracted period. This is due to the genetic mechanisms involved in the selection process. In a novel and partly successful attempt to find a solution to this problem, resistant *H. contortus* were diluted experimentally by spraying a susceptible strain onto pasture at different times in the grazing calendar. This approach however raises obvious ethical questions.

The FAMACHA system for managing *Hemonchosis* is a more easily applied field technique for reducing selection pressure for anthelmintic resistance. It was developed in South Africa and recently validated in the USA. It utilizes the fact that a high proportion of the total parasitic *H. contortus* population is found in just a small proportion of individual sheep within a flock. These will be the most anemic animals and will be shedding the greatest number of eggs onto the pasture. They are identified by comparing the ocular conjunctivae of each animal against a graded color chart. By confining treatment to these individuals, the general health of the flock is maintained with fewer anthelmintic doses, while pasture contamination is substantially reduced and is largely derived from untreated sheep.

**Natural resistance to gastrointestinal nematodes** can be enhanced by breeding from rams selected for low fecal egg counts. This provides a feasible method of reducing reliance on chemical control. Heritability for this trait, which is mediated by IgA-induced retardation of worm growth, is between 0.2 and 0.4. Selection for genetic resistance may however reduce capacity to select for other production attributes in some circumstances.

**Vaccination** is an attractive future possibility and considerable progress is being made in this direction. An experimental molecular vaccine based on an *H. contortus* gut membrane antigen has been shown to reduce fecal egg counts by 90% and worm numbers by 72–80%. Young lambs can be protected by the passive transfer of colostral antibodies from vaccinated ewes. There is no cross-immunity with other gastrointestinal nematodes and so anthelmintic therapy will still be necessary if these pose a health risk.

In poorer farming regions, the routine use of modern anthelmintics or vaccination may be prohibitively expensive and alternative sustainable methods are being sought. This may involve identifying more resistant indigenous breeds to replace more productive but more vulnerable imported breeds. Another option is the provision of a supplementary diet containing locally available protein. This enhances the ability of breeds more susceptible to *H. contortus* to withstand the pathogenic effects of infection and may be economically feasible in some agricultural systems. Some native forages contain substances, for example tannins, that are naturally deleterious to gastrointestinal worm populations. Alternate or mixed grazing systems can also be employed.

**REFERENCES**

ETIOLOGY

All farm animals other than horses harbor hookworms. The main species are:

- **Cattle**: *Bunostomum phlebotomum* is the most widespread but *Agrostomum vryburgi* may occur in cattle in Asia and South America
- **Sheep**: *B. trigonocephalum* is found worldwide while *Gaigeria pachysce/is* occurs in India, Indonesia, South America and Africa.

Additionally, *Globocephalus* spp. occur in pigs but are rarely of clinical importance.

LIFE CYCLE

Hookworms are reddish-colored nematodes, 1–2.5 cm long, and inhabit the small intestine of their hosts. The females are prolific egg layers and the lifecycle is direct. The eggs hatch and two free-living, non-parasitic larval stages follow, which are very susceptible to desiccation. An infective larva is produced in about 1 week under favorable conditions. Transmission is by skin penetration alone in the case of *G. pachysce/is* but *Bunostomum* spp. larvae can enter the body via the skin or the mouth. After cutaneous penetration, larvae:

- Enter the bloodstream
- Are carried to the heart and lungs
- Enter the alveoli where the fourth-stage larvae develop
- Pass up the air passages to the pharynx
- Are swallowed
- Reach the small intestine.

Ingested larvae penetrate the intestinal wall and return to its lumen without further migration. In *B. trigonocephalum* infestations, the fourth-stage larvae reach the intestine in about 11 days and egg-laying adults are present about 7 weeks after infestation. The prepatent period in *B. phlebotomum* infestations is about 8 weeks and in *G. pachysce/is* 10 weeks.

EPIDEMIOLOGY

The chances of infestation occurring by percutaneous entry are greatly enhanced when the surroundings are wet, and this, together with the susceptibility of the larvae to desiccation, leads to a higher incidence of the disease in humid subtropical or warm temperate countries such as the southern United States, Africa, northern Australia, and parts of Europe. Heavy infestations of sheep or cattle are uncommon in cooler temperate countries but do occur occasionally when animals are winter housed in dirty surroundings with insufficient bedding. Immunity to *B. phlebotomum* in cattle appears to develop with age and animals affected one year appear to be completely immune the next. Calves 4–12 months of age are most commonly affected and the degree of infestation is always greatest in the winter months.

PATHOGENESIS

Hookworms are active bloodsuckers and cause severe anemia in all animal species. Total worm counts as low as 100 may cause clinical illness2 and 2000 may cause death in young cattle. There is a loss of whole blood and hypoproteinemic edema may result. Some irritation to the intestinal mucosa is inevitable and mild or intermittent diarrhea follows. Penetration of the skin by larvae may cause signs of irritation and lead to the introduction of pathogenic bacteria.

CLINICAL FINDINGS

In mild infestations in stabled cattle, fidgeting, stamping, and licking of the feet may be observed. Constipation, accompanied by mild abdominal pain is seen in the early stages and is followed by bouts of diarrhea. The cattle are unthrifty and anemic. In severe infestations there are obvious pallor of mucosae, weakness, anasarca under the jaw and along the belly, prostration and death in 2–3 days. The signs in sheep are similar to those in cattle. The convalescent period, even after treatment, is prolonged unless the diet is supplemented to stimulate erythrocyte production.

CLINICAL PATHOLOGY

The eggs in feces are similar in appearance to many other gastrointestinal nematodes. Hookworm egg counts of 400–500 epg are usually associated with fatal infestations. As both larvae and adult worms are avid bloodsuckers, clinical signs are often evident before eggs appear in the feces. The degree of anemia and the presence of occult blood in the feces can be used as a measure of the severity of the infestation.

NECROPSY FINDINGS

Hookworms attached to the mucosa are easily found but they may be few in number. In calves, total worm counts of 100 or more suggest a significant level of infestation; counts of over 2000 worms indicate a degree of infestation likely to be fatal. In sheep and goats, 24 adult *G. pachysce/is* have been reported to be fatal, but the usual fatal figure is probably closer to 100. Most of the worms are found in the first few feet of the small intestine and the intestinal contents nearby are often deeply bloodstained. Hookworms often form part of a mixed infection comprising several or many gastrointestinal nematodes.

DIAGNOSTIC CONFIRMATION

Anemia, diarrhea, and anasarca are signs common to several diseases and necropsy is the only certain method of diagnosis.

DIFFERENTIAL DIAGNOSIS

- Hepatic fasciolosis
- Hemorrhage
- Coccidiosis
- Mycoplasma avis
- Dietary deficiency of cobalt or copper and chronic molybdenosis.

TREATMENT

Most newer broad-spectrum anthelmintics including the benzimidazoles, avermectin/milbemycins, levamisole, and moxalate are effective against adult *Bunostomum*
Etiology Nematomes of the genus Oesophagostomum. 

EPIDEMIOLOGY O. columbianum eggs and larvae are particularly susceptible to cold and dryness, but under optimum conditions can reach the infective stage in 6–7 d. Prevalence is therefore highest in warmer temperate or subtropical climates with summer rainfall. If sufficient larvae are ingested, acute disease may occur during the summer months. Lighter infestations or exposure of older animals to infection may give rise to a chronic condition that presents clinically in the following winter when animals are on a low plane of nutrition. Disease in cattle is similarly most common in warmer summer rainfall areas. Nevertheless, the more chronic form of the disease is quite common in ruminants in eastern Canada and the New England states of the United States. In pigs, Oesophagostomum infections are cosmopolitan. The female worms produce large numbers of eggs and in pig houses only the highest standards of hygiene will prevent infections from persisting. Outdoors, the larvae thrive best when sheltered by thick vegetation. Numbers decline markedly during dry summers on bare soil or during the winter. Some larvae, however, can overwinter even in Scandinavia, but cold Canadian winters kill all free-living stages. A periparturient rise in fecal egg counts has been described in sows but it is not as constant a feature as the similar phenomenon in ewes. The periparturient egg-rise (PPER) is closely related to lactation and terminates when the piglets are weaned. When it occurs, it can be an important source of contamination in the farrowing house. Oesophagostomum has been associated with the thin sow syndrome, in which sows rapidly lose condition late in pregnancy and while they are lactating. Fecal egg counts may be very high but parasitism is only a contributory factor. The primary cause is inadequate nutrition. In group-fed animals, timid sows not able to secure an adequate share of the ration satisfy their hunger by eating bedding, thereby increasing their intake of infective larvae.

PATHOGENESIS The size of the nodules in the intestinal wall, and hence their pathogenicity and economic importance to the meat industry, varies with the worm species and immunity of the host. In ruminants, for example, O. columbianum provokes a massive host response while O. venulosum does not produce visible lesions. In pigs, O. quadririspinalatum nodules are larger than those of O. dentatum. O. columbianum larvae in young sheep exposed for the first time stay in the wall of the anterior small intestine for about 5 d. Some subsequently enter the mucosa a second time in the large intestine, while others develop directly to adults. In second and subsequent infections, few larvae develop directly to adults and most are arrested in either the first or second mucosal phases. Persistence of larvae in the intestinal wall for long periods is thought to indicate host immunity, thus in older sheep, nodules develop in the intestinal wall at any level and may occasionally be present in nearby organs. Larvae may remain alive in these nodules for periods of up to 1 year but many are destroyed by the host response. When the resistance of the animal is lowered, due for example to poor nutrition, larvae leave...
the nodules, re-enter the intestinal lumen and pass down to the colon to become adults. This is the probable explanation for three common findings at necropsy:

1. Young sheep with many adult worms and no nodules
2. Adult sheep with many nodules and no adult worms
3. Adults with both.

Oesophagostomosis is sometimes implicated as a primary cause of intussusception in young sheep.

Young susceptible ruminants generally suffer as a result of the emergence of larvae from the mucosa, which provokes a catarhal colitis, and the feeding activities of the adults, which produce small ulcers and some mucosal bleeding. In older, immune animals the nodular reaction plays a more important role. O. radiatum and O. columbianum cause:

- Anorexia
- Severe and persistent mucoid diarrhea
- Loss of weight
- Anemia
- Hypoproteinaemia
- Death.

The hypoproteinaemia follows edema of the cecum and colon and is caused by loss of albumin into the lumen. Anemia results from blood loss when mucosal larvae re-enter the lumen. The fall in plasma fibrinogen levels and platelet numbers observed 6-7 days after primary infection of calves probably aggravates this loss. Nodules eventually caseate and calcify and may cause interference with intestinal motility or local peritonitis and adhesion formation, which leads to intussusception or stenosis. In sheep the nodules can cause considerable pain and result in an arched back (‘humpy back’) and a stilted gait. The nodules in pigs are much smaller, although edema and thickening of the colon and cecum can develop in the case of heavy infestation. Outbreaks of necrotic enteritis may be activated in pigs carrying Salmonella spp. populations.

CLINICAL FINDINGS

In heavily infested sheep, severe persistent diarrhea may occur in young animals. More commonly, older sheep in the winter months will show an intermittent passage of semi-soft droppings which contain excessive amounts of mucus and occasionally blood. There is rapid loss of condition, hollowing of the back, stiffness of gait and elevation of the tail. Nodules may be palpated on rectal examination. Anemia is not characteristic and is never marked.

Young calves may show anorexia, diarrhea, emaciation, and anemia. Initially the diarrhea may alternate with constipation, but later it is continuous and is dark and fetid.

In pigs, clinical signs are less severe. Loss of condition and diarrhea in weaners and growers have been attributed to heavy infection, but deleterious effects, if any, are normally found at a subclinical level. In the ‘thin sow’ syndrome, lactating sows become thin or in severe cases emaciated, even though they have a good appetite but there is usually no diarrhea.

CLINICAL PATHOLOGY

There are no specific laboratory tests. The eggs in feces are similar in appearance to those of many other gastrointestinal nematodes. Also, the severity of the disease may bear no relation to the number of eggs in the feces; counts vary widely with the season and the stage of development of the disease. In the early stages of a massive infestation, signs may be evident but there may be no eggs in the droppings. After the prepatent period in young sheep, eggs are usually present in large numbers and may be accompanied by living adult worms. In chronic cases however, very few eggs may be passed. Serum albumin concentrations are low in severe cases and anemia may be detected in cattle.

NECROSIS FINDINGS

In early acute cases there is a mild catarrhal enteritis and larvae may be detectable in scrapings of intestinal mucosa. In the later more chronic stage, adult worms are easily visible in the colon. They are usually lying in thick mucus overlying a chronic catarrhal colitis. O. columbianum is very pathogenic and 200 adult females is considered a heavy infestation. Nodules, when they are present, may be found at all levels of the intestine, they measure up to 6 mm in diameter and, depending on their age, contain green, pasty or yellow-brown, crumbly, partly calcified material. There may be a great deal of thickening of the intestinal wall and local peritonitis.

DIAGNOSTIC CONFIRMATION

A definite diagnosis of oesophagostomosis can only be made by necropsy examination or identification of larvae from a fecal culture.

DIFFERENTIAL DIAGNOSIS

- Trichostrongylosis in sheep is also at its peak during the winter but diarrhea is more evident.
- Hysterospygiosis also causes emaciation in lactating sows but is confined to outdoor herds.
- Malnutrition, especially when sheep are housed and poorly fed.

TREATMENT

All modern broad-spectrum compounds are effective against adult Oesophagostomum. Moxidectin provides up to 4 weeks’ protection from reinfection with O. columbianum in sheep. Oesophagostomum spp. strains resistant to pyrantel have been detected on some pig farms in Denmark.

CONTROL

In sheep and cattle, the principles of control described under parasitic gastroenteritis in ruminants apply also to Oesophagostomosis infections.

In pigs, the thin sow syndrome is unlikely to be cured or prevented by anthelmintic treatments alone; due consideration must also be given to the nutritional requirements of the animals at risk. To prevent contamination of the farrowing house, sows should be treated before entry. Pigs should be treated at weaning and each time they are moved on to new accommodation. Boars should be treated at least once a year. Alternatively, it may be more convenient to treat all pigs on a premises simultaneously with a medicated feed. The dosing interval should be determined by fecal egg-counts performed on a representative sample of all age groups in the herd. Overdependence on anthelmintic therapy should be avoided as resistance can develop in Oesophagostomum populations. The demonstration that diets containing highly degradable and rapidly fermentable carbohydrates can considerably reduce O. dentatum burdens and fecal egg-counts indicates the possibility of an alternative approach to control.

In grazing pigs, the ability of the eggs and larvae to survive on the pasture must be considered. In the United Kingdom, eggs deposited in the winter and early spring do not reach the infective stage but infective larvae can survive for a year in feces or on pasture. Under these conditions treatment of pigs in the autumn with a move to clean pasture will reduce pasture contamination through the following spring and early summer. An additional treatment in spring may give additional security.

REVIEW LITERATURE

REFERENCES

Parasitic gastritis in pigs

Etiology The nematodes *Hyostrongylus rubidus*, *Ascarops*, and *Physcocephalus*.

Epidemiology Infections occur in outdoor husbandry systems; *Hyostrongylus rubidus* has a direct lifecycle, but *Ascarops* and *Physcocephalus* use dung beetles as intermediate hosts.

Signs Generally asymptomatic but heavy infections can produce gastritis; sows with *H. rubidus* may become thin during lactation.

Clinical pathology Eggs of *Ascarops* and *Physcocephalus* in feces are characteristic; those of *H. rubidus* are similar to *Oesophagostomum*.

Lesions Excess mucus; gastritis; often ulceration of glandular part of stomach; nodular hyperplasia in hydrostrongylosis.

Diagnostic confirmation Demonstration of eggs of *Ascarops* or *Physcocephalus*; examination of larvae from fecal culture for *H. rubidus*.

Treatment *H. rubidus*: doramectin, ivermectin, fenbendazole, flubendazole, febantel, oxibendazole, thiophanate, levamisole, and dichlorvos; *Ascarops*: ivermectin.

Control Good husbandry practices, such as rotating pastures, normally suffice.

Clinical findings

The effect of *H. rubidus* on young pigs is not usually clinically apparent. Heavy infestations may be associated with anemia, unthriftiness, poor growth, and diarrhea. Signs in adult sows are usually seen during lactation. Affected animals lose more weight than normal and are slow to regain condition after weaning. In severe cases, sows may become emaciated. There may be pallor due to anemia and often a dehydrated appetite, but no diarrhea. Adult sows often carry heavy infestations without clinical illness but sudden death due to hemorrhage from gastric ulcers or to peritonitis by ulcerative perforation has been observed on rare occasions. Although *Ascarops* and *Physcocephalus* are common in many areas, most infections are low grade and without clinical effect. Heavy infections can lead to inappetence and other signs of gastritis.

Clinical pathology

Fecal examination is not very useful for the diagnosis of hydrostrongylosis as the eggs of *H. rubidus* are indistinguishable from those of the less pathogenic but more prolific *Oesophagostomum* spp. *Physcocephalus* and *Ascarops* spp. eggs are small, thick-shelled and contain a larva when laid.

Necropsy findings

The presence of *H. rubidus* is easily missed as the worms are slender and often lie beneath a thick layer of mucus. The gastric mucosa is hyperemic and nodular lesions are present. There may be one or more deep ulcers in the glandular region of the stomach. These may contain clusters of adult *H. rubidus*. In severe cases the mucosa is thickened and edematous, and covered with a diphtheritic pseudomembrane. In *Physcocephalus* and *Ascarops* infections, adult worms are readily visible lying in mucus on the gastric mucosa. There is an obvious gastritis in heavy infections and ulceration may occur.

Diagnostic confirmation

Confirmation of infection with *H. rubidus* is made by examination of larvae from fecal cultures. Those of *H. rubidus* are longer and more vigorously motile than those of *Oesophagostomum* spp. As *H. rubidus* produces so few eggs, even small numbers of larvae may indicate a pathogenic worm burden. Elevated serum pepsinogen concentrations may also be indicative of infection.

Differential diagnosis

*H. rubidus* must be differentiated from other causes of unthriftiness or emaciation such as:

- *Swine dysentery*
- Necrotic enteritis
- Coccidiosis
- Infestation with *Oesophagostomum* spp.
- Thin sow syndrome
- Malnutrition

Treatment

Doramectin (0.3 mg/kg by injection), ivermectin (0.3 mg/kg by injection or 0.1 mg/kg/d for 7 d in feed), fenbendazole (5 mg/kg in feed as a single dose or divided over 7-14 d) and flubendazole (5 mg/kg as a single dose or 30 g/t finished feed given for 5-10 d) are active against fourth-stage and adult *H. rubidus*. Additionally, febantel (5 mg/kg), oxibendazole (15 mg/kg or 1.6 mg/kg/d for 10 d) and thiophanate have label claims.
only for the adult worm. Levamisole and dichlorvos have also been widely used in the treatment of pig nematodes. In-feed ivermectin is also effective against *A. strongyloides*.

**CONTROL**

Standard hygienic precautions including frequent removal of manure, the provision of drainage in outside pens and rotation of pastures will reduce environmental contamination. Control of the dung beetle intermediate hosts of *Physcocephalus* and *Acarops* is impracticable.

Hyostrogyalosis is most likely to affect sows during lactation and so animals at risk should be dosed before farrowing.\(^5\) The behavior of *H. rubidus* larvae on pasture is similar to that described for *Oesophagostomum* and control schemes should be effective for both parasites.\(^6\)

**REVIEW LITERATURE**

**Ascarid infections in pigs, horses and cattle**

**Synopsis**

**Etiology** Nematode worms from the ascarid family: *Ascaris suum* in pigs, *Parascaris equorum* in horses and *Toxocara vitulorum* in buffalo and cattle.

**Epidemiology** Transmission is by ingestion of highly resistant and long-lived larvated eggs. *T. vitulorum* is also transferred via colostrum.

**Signs** Heavy infestation leads to poor growth and afebrile diarrhea, sometimes with obstructive jaundice, intestinal obstruction and respiratory signs.

**Clinical pathology** Characteristic eggs in feces and a marked eosinophilia.

**Lesions** Petechial hemorrhages in lungs and fibrotic spots on the liver.

**Diagnostic confirmation** Demonstration of characteristic eggs in feces.

**Treatment** Pigs: ivermectin, doramectin, flubendazole, febantel, oxibendazole, thiophanate, pyrantel tartrate, and levamisole. Horses: ivermectin, moxidectin, febantel, fenbendazole, mebendazole, oxibendazole, and pyrantel embonate.

**Control** Pigs, horses: Keep young stock away from sites where eggs may accumulate. Cattle/buffalo: prophylactic anthelmintic treatment of 10–16 day old calves.

**ETIOLOGY**

Each species has its own ascarid: *Ascaris suum* in pigs and *Parascaris equorum* in horses are cosmopolitan, while *Toxocara vitulorum* is an important cause of mortality in buffalo calves in India and Southeast Asia. Genetic studies show that although *A. suum* of the pig is very similar to *A. lumbricoides* of man, host-specific differences do exist and crossoffs occur only infrequently.\(^2\,5\) There is no ascarid specific for sheep but they may rarely become infected with *A. suum*.

**LIFE CYCLE**

*A. suum* and *P. equorum* have similar lifecycles. The adult worms are long (20–50 cm), cylindrical, pointed at both ends and have a thick, glistening, yellow-white cuticle. They live in the small intestine and lay very large numbers of thick-shelled eggs. These are not infective until a larva has developed inside. This process needs suitable warmth and humidity and takes place over a period of several weeks. When swallowed, infective eggs hatch quickly in the intestine of the host and the larvae migrate through the intestinal wall, reach the portal vein and are transported to the liver. They cross to the hepatic venous system and travel to the lungs, are passed up the bronchi and trachea to the pharynx, are swallowed and come to rest in the intestine where they mature. The prepatent period (time from infestation to the appearance of eggs in the feces) is 6–8 weeks for *A. suum* and 11–15 weeks for *P. equorum*.\(^4\)

*Toxocara vitulorum* has a more complex lifecycle. When eggs are ingested by cattle or buffalo more than 4–5 months of age, the larvae instead of traveling to the intestine settle in somatic tissues without developing or growing. Subsequently they become activated around calving and migrate to the udder. They transfer to the calf in the colostrum and grow to the adult stage in the intestine.

**EPIDEMIOLOGY**

In pigs and horses the only route of infection is by ingestion of larvated eggs. Because the eggs have very thick walls the infective stage is protected from deleterious environmental influences. Few disinfectants will harm them and they are very resistant to cold but survive most readily in cool, moist surroundings. Periods of survival of up to 5 years have been recorded. In the United Kingdom, *A. suum* eggs shed from September to May become infective more or less synchronously in July and the number of eggs becoming infective then falls away rapidly. This coincides with the prevalence of damaged livers recorded at bacon factories.\(^5\) Transmission is therefore seasonal but as ascarid eggs are very resistant and can overwinter, pigs and horses may in the absence of good hygiene become infected at all periods of the year.\(^6\) Clinical ascarosis is usually associated with conditions that allow infective eggs to accumulate. This may happen where, for example, the stocking rate is high and the same paddocks are used year after year, or when indoor pens are inadequately cleaned.

**Protective immunity** develops and consequently only the young are seriously affected. Under field conditions, eggs are passed by foals from 12–13 weeks of age and spontaneous expulsion of worms occurs 6–9 weeks later. Eggs are seen occasionally in the feces of very young foals but this is thought to be due to the ingestion of uninfected eggs during coprophagia. In older animals no clinical signs are observed but infested animals, particularly adult sows and yearling horses, continue to contaminate their surroundings and are an important link in the chain of infection.

*Toxocara vitulorum* larvae are present in greatest numbers in the colostrum 2–5 d after calving and few are present after day 9.\(^8\) Mature worms are present in the intestine of the calf by 10 d of age and eggs are passed by 3 weeks. Worms are expelled by 5 months of age, thus toxocarosis is a calfhood disease.

**PATHOGENESIS**

Migration of larvae through the liver results in hemorrhage and fibrosis, the latter appearing as white spots under the capsule. In heavy infection diffuse fibrosis may occur. The most serious damage occurs in the lungs where the larvae provoke alveolar injury with edema and consolidation. This damage can exacerbate pre-existing lung infections or provide a portal of entry into the body for pyogenic organisms. Immunity to migrating larvae is acquired and can be transferred through colostrum or immune serum.

**In animals other than pigs**, *A. suum* larvae migrate and develop but the worms do not normally reach the small intestine. During this process severe clinical signs of pulmonary involvement may appear. The disease has been produced experimentally in lambs and calves and has also been observed as a field occurrence in yearling cattle.\(^9\)\(^11\)

**Foals with *P. equorum*** have reduced gut motility, an increase in the ratio of body water to body solids and a lowering of the body pool of albumin.\(^12\)

**CLINICAL FINDINGS**

In pigs up to 4–5 months old, clinical signs associated with heavy infestation are poor growth, an afebrile diarrhea
and lowered resistance to other disease. There is some evidence that exposure to parasites during the growing phase without anthelmintic treatment causes permanent damage to growth potential.\textsuperscript{13} Adult worms may be vomited up and occasional cases of obstructive jaundice and intestinal obstruction or rupture occur. There may be coughing while larvae are passing through the lungs but this is not marked and there is seldom sufficient damage to cause a noticeable increase in respiratory rate or depth. In rare cases the infestation may be so severe that pigs manifest severe dyspnea or die of acute hepatic insufficiency. Enzootic pneumonia of pigs and swine influenza are reported to be much more serious diseases when accompanied by heavy \textit{A. suum} infections, and breaks in hog cholera vaccination with live virus have been attributed to this cause. \textit{A. suum} in other host species produces fever, dyspnea, and anorexia about the 8th day after infestation.\textsuperscript{9}

Effects in foals and calves due to heavy infestation with \textit{P. equorum} and \textit{T. vitulorum} are similar to those observed in young pigs and include poor coat, diarrhea, and occasionally colic. In addition, in foals, convulsions, intestinal obstruction, and perforation may occur. Lung damage may give rise to fever, coughing and a mucopurulent nasal discharge. In calves, anemia and steatorrhea are additional signs.

**CLINICAL PATHOLOGY**

Characteristic eggs are usually present in large numbers in the feces of clinically affected animals. A marked eosinophilia often accompanies the early stages of infestation in pigs and in other species and has been shown to persist in calves for at least 1 year.

**NECROPSY FINDINGS**

In the early stages of a massive infestation, there are subpleural hemorrhages, and edema and congestion of the lungs. The pleural cavity may contain blood-stained fluid. The liver is enlarged and congested and there may be hemorrhages under the capsule. Microscopically, necrotic tracts and sections of larvae are observed. In species other than the pig, infestation with \textit{A. suum} is accompanied by emphysema, alveolar wall thickening with fibrin, eosinophils and hemorrhage in the lungs, and necrotic tracts in the liver.

In chronic cases the capsule of the liver is marked with white spots of small diameter which may, in severe cases, be confluent and constitute a network of connective tissue. Histologically, the necrotic tracts have been replaced by fibrous tissue. The carcass is usually in poor condition and may be jaundiced. Large numbers of mature worms may almost fill the lumen of the small intestine.

**DIAGNOSTIC CONFIRMATION**

Ascarids are brown and have thick walls with a pitted surface. Fecal egg counts in excess of 1000 epg are considered to be indicative of significant infection. Migrating larvae are too small to be observed by the naked eye at postmortem examination. They can be recovered from macerated lung tissue by the Baermann technique or seen microscopically in scrapings of bronchial mucus.

**DIFFERENTIAL DIAGNOSIS**

**Early stages of massive infection:**
- Enzootic pneumonia in pigs
- Chronic form of \textit{Rhodococcus equi} pneumonia in young foals
- Other forms of pneumonia in calves.

**Chronic infection:**
- Other causes of unthriftiness including malnutrition and chronic enteritis due to infections with \textit{Salmonella} and \textit{Brachyspira} spp.

**TREATMENT**

**Pigs**

In pigs, ivermectin or doramectin at 0.3 mg/kg and flubendazole 5 mg/kg are effective against adult and fourth-stage (intestinal) larvae of \textit{A. suum} while fenbendazole 5 mg/kg, febantel 5 mg/kg, oxibendazole 15 mg/kg, thiophanate, pyrantel tartrate, and levamisole are effective against the adult worm. Ivermectin, fenbendazole, flubendazole, tiophanate, and pyrantel may be given in feed as divided doses over several days. Ivermectin may have some activity against migrating larvae.\textsuperscript{14}

**Horses**

In horses, ivermectin 0.2 mg/kg, moxidectin 0.4 mg/kg, febantel 6 mg/kg, fenbendazole 7.5 mg/kg, mebendazole 5–10 mg/kg, oxibendazole 10 mg/kg, and pyrantel embonate 19 mg/kg are all effective against adult \textit{P. equorum}. Ivermectin, moxidectin, and fenbendazole are also active against immature forms in the intestine.

**Buffalo calves**

In buffalo calves, the limited data available suggest that pyrantel has good efficacy against both immature and adult worms. A dose of 250 mg for a calf has given good results.\textsuperscript{8} Other compounds such as levamisole, febantel, oxendazole, and even piperazine can be used for treatment but may not expel all worms.

**CONTROL**

Important lifecycle features which must be taken into account when devising a control program for ascarid infections are:

- The worms are prolific egg layers
- The infective eggs are very resistant and long lived
- Young animals are most susceptible.

Emphasis must be placed on preventing the environment from becoming contaminated. This is achieved by periodic treatment of the animals likely to be shedding eggs— asymptomatic adult carriers as well as the more vulnerable young stock. Exposure of young pigs and foals to contaminated soil or bedding should be avoided.

Unnecessary treatments can be avoided by regular monitoring with fecal egg counts. In intensive pig-raising systems on concrete floors, the risk of ascarid infestation can be greatly reduced, but rarely eliminated, with good standards of hygiene. In the case of straw yards, epidemiological studies in the United Kingdom\textsuperscript{9} suggest that all bedding should be removed at the end of June (to remove eggs shed in preceding months before they become infective) and again at the end of August (to remove eggs deposited in the summer). If pigs are allowed access to small earthen yards, these must be kept well drained and the manure removed frequently. Control is difficult in free-range systems as the eggs become infective in 4–6 weeks in summer and many persist over the winter.\textsuperscript{15} Deep ploughing of contaminated soil after use will reduce risk of \textit{A. suum} and \textit{Trichuris suis} eggs infecting future batches of pigs.

If farrowing pens are regularly cleaned with high-pressure water and sows are treated immediately prior to entry, it may be possible to control infection in piglets without anthelmintic treatment. Breakdowns may occur as ascarid eggs are adhesive and not all will be washed away by hosing. For the same reason, eggs are easily introduced from outside on boots etc. It may therefore be necessary to treat piglets at weaning. Ascarids may be controlled in growing pigs by periodic anthelmintic treatments, but this has to be combined with rigorous hygiene to eliminate liver damage caused by migrating larvae.

Young foals present more of a problem as they often run on permanent pasture used by foals in previous years. Such pastures may become heavily contaminated with eggs. Recommendations for control include\textsuperscript{16}:

- Thorough cleaning and disinfection of the maternity stall after each foaling
- Use of small exercise paddocks which should preferably have been rested from occupation by horses for a year
- Weekly removal of manure from the pasture. The foals should be routinely treated at about 10–12 weeks of age
when the worms are first becoming mature and again at bimonthly intervals. In this way heavy egg contamination of the pasture can be avoided.

Early signs of the possible development of anthelmintic resistance in *P. equorum* are starting to appear.17

In buffalo calves, a single anthelmintic treatment at 10–16 d of age using a compound with high activity against larval stages gives good control of *T. vitulorum*.

**REVIEW LITERATURE**

Postgraduate Foundation in Veterinary Science University of Sydney Australia, 1985.

**REFERENCES**

---

**Strongylosis (redworm infestation) in horses**

**Synopsis**

Etiology Two nematode subfamilies: the Strongylinae (large strongyles) and Cyathostominae (known variously as small strongyles, small redworms, trichonomes, cyathostomes, or cyathostominos). The species belonging to genera including *Strongylus vulgaris*, *S. edentatus*, and *S. equinus*, which migrate extensively through the body, and *Triodontophorus* spp. and *Oesophagodontus robustus*, which do not. The cyathostominos comprise more than 40 non-migratory species belonging to genera including *Cylcocephalus*, *Cylcoclypus*, *Cylciodontophorus*, *Poteriostomum*, *Cylocephalus*, and *Cylindrocyclus*.

**LIFE CYCLE**

Eggs are shed by horses of all ages; the lifecycle is direct; infective larvae develop seasonally on pasture; hypobiotic cyathostomin larvae can cause severe disease when they resume development in late winter.

**Clinical pathology** Strongyloid eggs in feces (except disease caused by larvae); reduced hemoglobin, erythrocyte counts and packed cell volumes, leukocytosis; eosinophilia (with migrating larvae); hyperglobulinemia, particularly IgG(1); hypoalbuminemia.

**Lesions** General strongylosis: large numbers of adult worms in cecum and colon; hemorrhagic inflammation of mucosa with multiple small ulcers, large and small nodules. Larval cyathostomosis: mucosa grossly inflamed with large numbers of larvae appearing as brown specks. Verminous arteritis: wall of cranial mesenteric artery greatly thickened, organizing thrombi and larvae on internal surface; ischemia or necrosis of parts of intestinal wall due to emboli. Migratory larvae: seen in various subserosal sites; some cause nodules in the liver.

**Diagnostic confirmation** Few pathognomonic indicators; judgment made on overall appraisal of clinical history, presenting signs and laboratory findings; arteritis of cranial mesenteric artery sometimes palpable per rectum; immature worms sometimes in feces of larval cyathostomosis.

**Treatment** General strongylosis: ivermectin, moxidectin, benzimidazoles, e.g. febantel, fenbendazole, mebendazole, oxibendazole, pyrantel. Migrating strongyles: ivermectin, moxidectin, fenbendazole (special dose). Larval cyathostomosis: fenbendazole (special dose), moxidectin.

**Control** Twice-weekly removal of feces from pastures; mixed or alternate grazing, routine dosing to prevent contamination of pasture with eggs. Larval cyathostomosis: 5-day preventive fenbendazole treatment in early winter.

**ETIOLOGY**

The redworms (strongyles) are nematodes commonly found in the large intestine of horses and other Equidae. They belong to two subfamilies: the Strongylinae (large strongyles) and Cyathostominae (known variously as small strongyles, small redworms, trichonomes, cyathostomes, or cyathostominos). The season of the year and pack conditions encourage larvae to migrate onto pasture. The lifecycle of all species is direct; horses become infected by ingestion of the infective larvae.

After ingestion, the larvae of non-migratory strongyloses, such as the cyathostomins, exsheath and enter the walls of the cecum and colon, where they remain in small subserous nodules for 7–38 weeks before breaking out into the lumen of the intestine. The time spent in the mucosa depends on:

- The species
- The season of the year
- The age and degree of immunity of the host.

They can become arrested in their mucosal development and their synchronous emergence some weeks later may provoke severe clinical signs. This may occur spontaneously, particularly in late winter, or may be induced by anthelmintic treatment. Expansion of the adult worm population seems to remove an inhibitory feed-back mechanism and may provoke clinical signs. Hypobiotic early third stage larvae are present in the mucosa at all seasons of the year.

**Larvae of S. edentatus** penetrate the intestine and travel via the portal vessels to the liver, where larvae remain and produce hemorrhagic tracts for a month or so. They then migrate via the hepatoportal ligament to the connective tissue under the peritoneum and form hemorrhagic nodules. After about 3 months, they return via the root of the mesentery to the large bowel wall and again form hemorrhagic nodules, which finally rupture and release the worms into the lumen. Adult egg-laying females are present from 40 weeks. Larvae may be found in other organs, e.g. the testes, but these larvae do not return to the intestine. *S. equinus* migrates via the liver to the pancreas and peritoneal cavity but how they return to the intestine is uncertain.

**Larvae of S. vulgaris** penetrate the intestinal wall, molt to the fourth larval stage in the submucosa and then pass into and up small arteries. By day 14, they have reached the cranial mesenteric...
artery, where they develop to late fourth-stage larvae. In 3-4 months they molt and the young adults then return to the intestine via the lumina of the arteries. Nodules are formed in the intestine wall and later rupture, releasing adults into the lumen of the intestine. The prepatent period is 6 months.

EPIDEMIOLOGY

Strongylosis is a common disease of horses throughout the world and causes deaths when control measures are neglected. In areas with cold winters and mild summers, egg deposition peaks in spring and remains high over summer. At this time, temperatures are suitable for larval development and massive contamination of infective larvae may occur in late summer and early autumn, when young susceptible horses are present. S. vulgaris larvae can overwinter in considerable numbers in Europe. If the summers are hot and dry, only a small proportion of strongyle eggs develop to larvae and these may be short-lived, but continual reinfection keeps pasture contamination high.

In subtropical regions, eggs can hatch throughout the year and larval availability is influenced more by rainfall than temperature. For example, in Florida in the United States, fecal egg counts remain high throughout the year and there is an autumn rise in infective larvae. Such associations between disease risk and local climate have important implications in the timing of treatments.

The onset of disease following ingestion of large numbers of larvae depends on the maturation period of the parasite in the host and whether it is the immature or adult stages that are pathogenic. Outbreaks of disease due to the emergence of small strongyles after hypobiosis are commonly seen in Europe in late-winter and early-spring (winter or larval cyathostomiasis), while arterial lesions due to larval S. vulgaris are first seen in late summer and reach a maximum by midwinter.

Mares are the main source of infection for younger horses as many adults carry appreciable strongyle burdens and pass large numbers of eggs. Nevertheless, horses do gain some acquired immunity to infection and so young stock are the most susceptible. Possibilities for vaccination are being investigated but a commercial product seems an unlikely prospect in the short term.

The extensive use of anthelmintics with high efficacy at regular intervals has resulted in a marked decline in the prevalence of S. vulgaris in many regions. The cyathostomins, on the other hand, are becoming increasingly important. This may be due to any of the following factors:

- Insusceptibility of mucosal cyathostomins to many drugs
- Selection for benzimidazole-resistant worms
- Selection for shorter egg reappearance periods.

PATHOGENESIS

The disease processes associated with the strongyles can be divided into those produced by migrating larvae, those provoked by the mass emergence of mucosal larvae and those associated with adult worms. Heavy intestinal infection can alter intestinal motility, permeability, and absorption.

The larvae of S. vulgaris are the most pathogenic, causing arteritis, thrombosis and thickening of the wall of the cranial mesenteric artery. Emboli may break away and lodge in smaller blood vessels, leading to partial or complete ischemia in part of the intestine, thus producing colic. The result of this depends on the length of the segment of intestine affected and the ability of the collateral blood supply to become established before necrosis and gangrene occur. It is not clear whether the ischemia is due directly to the mechanical effects of embolism or to consequent pathophysiological events. Whatever the cause, greatly enhanced mobility proximal to the lesion follows and can cause volvulus or torsion. Intussusception is seen occasionally. Colic may also be caused by pressure of the thickened cranial mesenteric artery on the mesenteric plexus.

Other arterial lesions associated with migrating S. vulgaris larvae include aneurysm of the cranial mesenteric artery but this is a relatively rare occurrence. More often, larvae aberrantly migrating beyond the cranial mesenteric artery cause migratory tracts and thrombi in other blood vessels. Multiple lesions may be seen in the cecal and colic arteries which may completely occlude the lumen and cause gangrene in parts of the bowel. Smaller lesions are occasionally seen in iliac, renal, splenic, hepatic and coronary arteries. Aortic and iliac thrombosis may result in hind-limb lameness. Field and experimental cases of cerebrospinal nematodiasis due to S. vulgaris invasion of the central nervous system have been reported.

Strongylus sp. larvae returning to the intestine cause large nodules in the wall of the cecum and colon. Considerable hemorrhage may follow when these rupture to release the worm into the lumen of the intestine. In very heavy burdens, bleeding sufficient enough to cause death can occur.

Developing cyathostomin larvae provoke the formation of small nodules which may be superficial or submucosal, depending on species. In heavy infections, the emergence of large numbers of larvae over a short period causes inflammation of the cecum or ventral colon, with small ulcers where larvae have emerged. Hemorrhages of varying sizes and excess mucus production. Typically, this leads to weight-loss, diarrhea and sometimes a variety of other clinical manifestations including colic and cecocoeal intussusception. Affected animals may sometimes secrete Salmonella.

Adult strongyles can be divided into those that cause blood losses and those that are superficial tissue feeders. Strongylus spp. have large buccal cavities which they use to draw in and digest plugs of mucosa, while secreting anti-coagulants to aid the ingestion of blood. Hemorrhage continues from feeding points after worms detach to find a new attachment site. Triodontophorus spp. and O. robustus feed similarly but are less harmful as they have smaller buccal capsules. An exception is T. tenacissilis as this species attaches in groups in the right dorsal colon and can cause large ulcers. The small strongyles (cyathostomins) have even smaller buccal cavities and produce only superficial damage so that even relatively large numbers (tens or hundreds of thousands) of adults often cause little apparent harm.

CLINICAL FINDINGS

In natural infestations it is often impossible to quantify the effects of individual strongyle species as the clinical picture usually represents the combined effects of a mixed infestation. Ill-thrift, poor hair coat, impaired performance, weight loss and anemia are signs associated with a ‘wormy’ horse. The greatest losses are probably due to the failure of young horses to grow optimally and the less efficient performance of moderately parasitized working horses and donkeys.

Clinical syndromes caused by arteritis in the cranial mesenteric artery, aorta and iliac artery are described in other chapters. Experimentally, the migratory phase of S. vulgaris infection is associated with pyrexia, inappetence, depression, leukocytosis, and intermittent or continuous colic. In more chronic cases there is a:

- Persistent low-grade fever
- Poor appetite
- Intermittent colic
- Poor weight gain.

Diarrhea may be present. Adult mares exposed to heavy S. vulgaris in late pregnancy may become very weak to the
point of recumbency. On clinical examination the mucosae are pale, the heart rapid and loud and respiration more rapidly increased. Intestinal sounds are increased although the feces are normal. Abortion may occur and the mare usually dies.

The simultaneous maturation of large numbers of hypobiotic larvae induces the condition known as winter or larval cyathostomiasis. This is usually characterized by rapid loss of weight, often accompanied by sudden onset diarrhea which becomes chronic. Subcutaneous edema frequently occurs. Numerous cyathostomin larvae may be passed with the feces or may be seen adhering to the glove after rectal examination. Larval cyathostomiasis can occur in horses of all ages but occurs most commonly in adults under 5 years old. Unless treated early, prognosis is guarded.

CLINICAL PATHOLOGY
Examination of feces for strongylid eggs confirms the presence of adult strongyles but does not differentiate species. To do this it is necessary to hatch the eggs and examine the infective larvae. This has to be done by an expert parasitologist and delays results by at least 10 d. Experimentally, specific amplification of ribosomal DNA in feces can be used for the detection and identification of strongyle infections and may lead to diagnostic tests.22

Hematological values, particularly reduced hemoglobin levels, erythrocyte counts and packed cell volumes are often taken as a non-specific indication of the degree of infestation with strongyles. Leukocytosis is a feature of heavy infection while eosinophilia may reflect the presence of migrating larvae. Serum analysis reveals a marked increase in beta-globulins, particularly IgG(T), and a decrease in albumin.23

NECROPSY FINDINGS
Adult strongyle worms may be seen attached to or close to the mucosal surface. The three Strongylus spp. are red in color and 2–5 cm long. Triodontophorus and Oesophagostomum are smaller, up to 2 cm. Less easy to see are the small strongyles (cyathostomins) which are more slender and generally under 2 cm long with smaller buccal capsules. Because most cases of strongylosis are caused by mixed infestations with all genera, necropsy findings usually include most of the lesions characteristic of each worm.

In cases of general strongylosis, very large numbers of adult worms will be found in the cecum and colon. There may be so many that they appear to form a living cover to the contents of these organs. Catarhal, hemorrhagic or fibrinous inflammation of the cecum and ventral colon with multiple small ulcers is associated with the emergence of cyathostomin larvae. There may be edema with excessive mucus production or numerous punctate hemorrhages. Fewer adult worms may be present in winter cyathostomiasis but large numbers of larvae (several per cm²) can be seen as brown specks in the mucosa, especially if this is illuminated from behind. Adult T. tenueculis are often found in large numbers in the right dorsal colon in association with small circular hemorrhages, and they are sometimes attached in groups at the base of deep mucosal ulcers.

Strongylus larvae occur in many subserous sites, especially in nodules in the intestinal wall, and the body cavities may contain an excess of blood-stained fluid. Verminous arteritis lesions of varying size associated with S. vulgaris are common at the root of the cranial mesenteric artery and occasionally in the iliac artery. The affected arterial wall is greatly thickened and contains loculi on its internal surface, many of which contain living larvae. Lamellated thrombi are also common at this site and these are sometimes infected. The thickening of the arterial wall often extends along the cecal and colic arteries and complete occlusion of these may be followed by gangrene of a segment of intestine. Similar lesions of arteritis may be present at the base of the aorta. Spontaneous rupture of the vessel occasionally occurs. A significant correlation has been reported between lesions in the proximal aorta and the presence of focal ischemic lesions in the myocardium.25 These are thought to be caused by microembolization causing arteriosclerotic lesions in the myocardial arterioles.

Larvae of S. edentatus cause hemorrhagic tracts and nodules in the liver and adhesions and disruptions of omental architecture. Hemorrhagic nodules 1–3 cm in diameter are produced in the subperitoneal region and these are reported to cause colic and anemia.

DIAGNOSTIC CONFIRMATION
A specific diagnosis is difficult to achieve in every case. Few clinical observations or laboratory results are pathognomonic for the disease syndrome associated with strongylo infection. Often a judgment has to be made on an overall appraisal of clinical history, presenting signs and laboratory findings. For example, only 7 out of 14 cases of larval cyathostomiasis were diagnosed ante-mortem in a series of adult horses with chronic diarrhea investigated at university referral clinics.21

A diagnosis of general strongylosis should be considered when poor growth, inappetence, diarrhea and some degree of anemia are the presenting signs. It is generally accepted that strongylosis is an important cause of anemia in horses. Fecal egg counts are generally high (over 800 epg) but are difficult to interpret. They have little direct correlation with worm burden as they are influenced by immunity and species composition. Also, they do not differentiate between different strongyle genera nor between these and Trichostrongylus axei infection of the stomach. In foals, eggs observed during the first few weeks of life are obtained by coprophagia and are not indicative of a patent infection.

The diagnosis of verminous arteritis also presents difficulty. The thickening of the cranial mesenteric artery may be palpable per rectum; the artery is situated below the aorta at the level of the posterior pole of the kidneys. Low serum albumin and increased beta-globulins particularly IgG(T) are the most useful laboratory tests while arteriography may demonstrate lesions in a number of arteries. Transrectal ultrasonography may also be useful.27

In larval cyathostomiasis marked weight loss, diarrhea, leukocytosis, hyperglobulinemia and hyperalbuminemia are usually seen. Peripheral edema is present in a proportion of cases. Fecal egg counts may be low or zero as it is the immature stages that cause this disease and owners have often wormed the animal before advice is sought. Consequently, serological diagnostic tests utilizing larval-antigen specific IgG(T) are under development.28

**DIFFERENTIAL DIAGNOSIS**

**General strongylosis:**
- Other causes of anemia in the horse, including:
  - Babesiosis
  - Equine infectious anemia
  - Dietary deficiency in stabled stock and the effect of racing for long periods
- Other causes of ill thrift in horses, including:
  - Ascarisis in the foal
  - Gross nutritional deficiency or agalactia in the mare

**Larval cyathostomiasis:**
- Other causes of chronic diarrhea including:
  - Other parasitic infections, particularly migratory strongyles
  - Granulomatous enteritis
  - Alimentary neoplasia
  - Salmonellosis
  - Chronic liver disease
  - Peritonitis
  - Sand enteropathy
  - Hyperlipidemia.
TREATMENT

Treatment may be targeted against immature and adult large and small strongyle worms in the lumen of the intestine, against migrating Strongylus larvae, particularly S. vulgaris or against cyathostomin larvae in the intestinal mucosa. The latter may be developing third or fourth stage, or hypobiotic early third stage larvae. Anthelmintics vary in their efficacy against these larval stages. This influences the egg reappearance period (i.e. the time from treatment to the reappearance of eggs in the feces as new adult worm populations establish). This in turn determines the treatment interval in control programs.

For elimination of adult worms there is a wide choice of compounds and formulations for use in feed, as pastes or by tubing. Most of these however belong to just three chemical groups:

1. Avermectin/milbemycins, also known as macrocyclic lactones, (ivermectin 0.2 mg/kg, moxidectin 0.4 mg/kg)
2. Benzimidazoles (febantel 6mg/kg, fenbendazole 7.5 mg/kg, mebendazole 5–10 mg/kg, oxibendazole 10 mg/kg)
3. Tetrahydropyrimidines (pyrantel 19 mg pyrantel embonate (pamoate)/kg or 6.6 mg pyrantel base/kg).

Cyathostomin populations resistant to the benzimidazoles are common in many countries. Such populations are sometimes, but not always, susceptible to oxibendazole. A resistant population may be slow to revert, as parasites were still resistant in one study after non-benzimidazole compounds had been used for 3 years. Pyrantel-resistant strains are becoming increasingly common but there is little evidence of ivermectin resistance after 20 years of use. Where resistance to any of the three groups is a problem, the choice of effective anthelmintics can be extended by use of products containing piperazine, which may be synergized with phenothiazine. An alternative to use of these products is the cautious use of selected organophosphorus compounds such as dichlorvos or haloxon (which should not be given to foals).

Mucosal cyathostomin larvae are more problematic. Publications on this topic are difficult to interpret as results may be influenced by experimental design and methodology. Moxidectin 0.4 mg/kg has activity against hypobiotic and developing third-stage larvae as well as the fourth stage. Consequently, this compound has a prolonged egg reappearance period allowing a treatment interval of 13 weeks for prevention of egg output onto pasture. Ivermectin seems at best to be variable in its activity against mucosal stages and a treatment interval of 8–10 weeks is generally recommended. Other anthelmintics at adultidose doses have little or no effect on mucosal cyathostomin larvae and treatment intervals of 4–6 weeks are necessary during periods of heavy pasture challenge.

Fenbendazole at a single dose of 30 mg/kg or, more reliably, 7.5 mg/kg daily for 5 d is efficacious against mucosal larvae. One study has shown the latter treatment program to kill over 90% of hypobiotic and 95–99% of normally developing mucosal larvae. The 5-day treatment is used in the early winter to prevent larval cyathostominosis. A second treatment may be required later in the winter if animals have continued access to contaminated pasture.

CONTROL

Eradication of all horse strongyles is not feasible as infections are ubiquitous and no drug currently available can completely eliminate the mucosal larvae. Adult horses can pass substantial numbers of eggs throughout their lives, stocking densities are often high and foals usually graze with their dam. Infective larvae on grass can be long lived and there are usually few opportunities for the long-term resting or reseeding of pastures on horse farms. Consequently, the primary objective of control programs is to minimize the numbers of infective larvae accumulating on pasture. There is no pasture treatment that is economically or environmentally acceptable. The possibility of using nematophagous fungi that will destroy larvae in the feces is an exciting prospect. Options for control by grazing management are limited. Alternate or mixed grazing with ruminants can reduce pasture infectively as horse strongyles will not establish in these hosts. The stomach worm T. axei however is a shared parasite. Removal of all horse feces from fields twice weekly is highly effective provided heavy rainfall does not disperse the material. This approach can be cost effective where valuable animals are at risk or labor is relatively inexpensive. Tractor-mounted mechanical devices are available for this purpose. A further benefit of fecal removal is that the area within the field grazed by the horses is enlarged i.e. the ratio of lawn to rough increases. Harrowing is effective in hot, dry conditions when eggs and larvae are quickly desiccated but at other times is likely to have a deleterious effect by spreading infective larvae.

Prophylactic chemotherapy is employed to a greater or lesser extent at most stables as land and labor constraints often limit the effectiveness of non-chemical approaches. The latter should nevertheless be used wherever possible to minimize the number of treatments needed during the year, which in turn reduces the risk of development of anthelmintic resistance. The purpose of prophylactic chemotherapy in the control of strongylosis is to prevent the output of strongylid eggs onto the pasture. Under conditions of heavy pasture challenge, regular dosing at 4–6 weeks with benzimidazoles or pyrantel, 8–10 weeks with ivermectin, or 13–16 weeks with moxidectin is necessary throughout the period of risk. Once pasture larval counts have been reduced to insignificant levels, the time between doses can be extended. Routine fecal egg counts are an important component of any control strategy as they are a direct measure of the rate at which pasture contamination is taking place. They also confirm the continuing efficacy of the drugs used and can be used to determine optimum treatment intervals.

Parasitism is a herd problem and all horses on a property should be treated simultaneously, even if they have different owners. If routine fecal examinations are performed, dosing can be restricted to those horses with significant egg counts. Untreated animals then provide parasite refugia for conserving anthelmintic efficacy. As horses and ruminants generally harbor different worm parasites, disease risk can be reduced by grazing these species together or by alternating the use of paddocks between each species. As most eggs are deposited on the pasture in spring and summer in temperate regions, concentration of treatments at this time should reduce contamination and give much lower pasture larvae counts in the following autumn and winter. Intensive treatment programs are often adopted on stud farms, where maximum reduction of contamination is required. Less frequent dosing may be necessary on properties with lower stocking intensities or where horses are run with other stock. As the mare is the main source of contamination for the foal, she should be treated about 2 months before foaling, again at foaling and regularly thereafter. Treatment of foals should commence at 10 weeks of age to remove small strongyles before they start to lay eggs, and should be repeated at intervals depending on the choice of drug.
An alternative strategy for maintaining low pasture infectivity is use of continuous low-level in-feed prophylactic therapy with pyrantel tartrate 2.64 mg/kg/d. This has been shown to control cyathostominis effectively but may be less reliable in foals against large strongyles.\(^1\) Treated foals may be more sensitive to the effects of others in that chemical group.

Delivering the onset of resistance is an important consideration in the design of any control program. The major equine anthelmintics belong to just three chemical groups and worm populations resistant to one compound are usually insusceptible to, or more tolerant of, the effects of others in that chemical group. The level of resistance in a herd can be estimated by means of the fecal egg count reduction technique (FECRT). At least six horses with high egg counts are weighed (eg. with a weigh band) and treated with an accurately measured dose of anthelmintic. A reduction in mean egg count after 7–14 d of less than 90% is suggestive of resistance. More stringent tests are required for confirmation. Recommendations for extending the useful life of existing products similar to those listed earlier for ruminants have been published for horse anthelmintics.\(^2\)

**Miscellaneous roundworm infestations**

OXYURIS EQUI (PINWORM)

Oxyuris equi is a nematode that provokes irritation of the perianal region of horses, causing them to rub and bite their tails. This can result in hair loss and sometimes physical damage to the tissues of the area. The parasite is ubiquitous but of greater prevalence in areas of high rainfall.\(^3\)

The life cycle is direct. The mature worms are gray in color and inhabit the rectum and colon. The male is 1–2 cm long, but the female is much longer, up to 15 cm, and has a long tapering tail. When full of eggs, the female migrates down the gut and crawls onto the perianal area, where she excretes her eggs onto the skin in yellow clusters and then shrivels up and dies. An embryo develops in about 3 d within the egg which is then infective. Eggs may be licked off the skin and swallowed or they may eventually fall to the ground. They resist desiccation, may become airborne in dust and remain viable in stables for long periods. Transmission then occurs via contaminated feedstuffs.

Diagnosis is by detection of operculated eggs, slightly flattened on one side, on transparent adhesive tape that has been pressed against the perianal skin and then placed on a microscope slide for examination, or by the chance observation of an adult worm in the feces.

Treatment comprises the application of a mild disinfectant ointment to the perianal region and the administration of ivermectin, moxidectin, any of the newer broad-spectrum benzimidazoles or pyrantel at the standard dose rate for horses. Piperazine salts are also effective.

**STRONGYLOIDES (THREADWORM)**

Farm animals in many countries are exposed to infection with the nematode genus Strongyloides. Disease outbreaks occur in young pigs, foals, calves, and lambs but the overall economic importance of this parasite does not appear to be very great. Different species occur in each host: Strongyloides ransomi in pigs, S. westeri in horses, and S. papillosus in sheep and cattle. All are parasites of the small intestine. They are thread-like and less than 1 cm in length.

**Only female worms** are present in the intestine and so eggs are produced by parthenogenesis. The eggs are thin shelled and contain an embryo. The larvae that hatch out may develop into infective or non-parasitic forms. The latter become free-living males and females which live in decaying organic material and produce fertilized eggs that give rise to infective larvae. Transmission occurs when infective larvae enter the host either by ingestion or by skin penetration. In older animals they accumulate in subcutaneous tissues and migrate to the mammary gland where lactation starts.\(^4\) Neonates are thereby infected via the milk and egg-laying females may be present in the intestine from about 1 week after birth. Infective larvae penetrating the skin of young animals travel via the blood to the lungs, where they break into alveoli, ascend the air passages to the pharynx and are then swallowed.

**Diarrhea in young animals** is the most common clinical sign but the passage of massive numbers of larvae through the skin may also provoke dermatitis. Experimental infections in calves cause pallor and coughing\(^3\) but cases of sudden death without previous symptoms have been ascribed to heavy burdens with many migratory larvae.\(^5\) In bulls, balanoposthitis may be seen. In lambs, dermatitis, pulmonary hemorrhage, and enteritis occur. Sheep may also develop lameness or be more susceptible to foot rot when subject to heavy infestations. Experimental infection of young goats produced transient diarrhea, dehydration, cachexia, gashing of teeth, foaming at mouth, anemia and nervous
signs. Pigs may show anorexia, listlessness and anemia but diarrhea is the principal clinical sign. Infestation in pigs has been shown to reduce intestinal enzyme activity, to increase intestinal plasma and blood loss and to reduce protein synthesis in the liver. In foals, high egg counts may be recorded in apparently healthy animals but may coincide with the onset of diarrhea (independent of the first heat of the mare) in other individuals. Episodes of frenzy in foals lasting approximately 30 min have been attributed to percutaneous larval invasion. Within 2 days skin lesions developed on the lower limbs which persisted for 2–3 weeks.

Most broad-spectrum anthelmintics are effective in eliminating this parasite. In foals, ivermectin is used at the standard equine dose but elevated doses of fenbendazole (50 mg/kg) and oxibendazole (15 mg/kg) are needed. The treatment of mares with ivermectin on the day of parturition did not prevent transmammary transmission but markedly reduced egg counts in the foals. Treatment of infected sows was effective in removing arrested larvae from the subventral fat. Use of the ivermectin controlled-release bolus in lambs prevented establishment of intestinal Strongyloides infections.

Control depends on the elimination of warm, moist areas such as damp litter or bedding, suitable for parasite multiplication.

TRICHURIS (WHIPWORM)

Three species of whipworms are found in ruminants: Trichurus ovis, T. discolor, and T. globolosa, while T. suis occurs in pigs. Whipworms in farm livestock are usually considered to be relatively innocuous. Indeed, induced T. suis infections are being evaluated in human medicine for amelioration of chronic inflammatory bowel disease, since whipworm induced Th2 immune responses dampen harmful Th1 activity in some patients. Heavy infestations can nevertheless produce serious disease with diarrhea and dysentery and the mortality rate can be high in recently weaned pigs. Severely affected animals are anorexic and rapidly lose weight. The feces may contain blood-stained mucus and strips of necrotic mucosa. The nematodes lie with their thin anterior end superficially embedded in the wall of the cecum and in heavy infections the colon may also be involved. The activities of the worms produce little tissue reaction per se but enable microorganisms in the gut microflora to become invasive. This is the main cause of the severe inflammation and clinical signs associated with whipworm infestation. A synergia has also been demonstrated between T. suis and Campylobacter jejuni.

The life cycle is direct. The eggs are very resistant to external environmental conditions and can survive for up to 6 years in old pigsties, and for at least 2 years on pasture in the south of England. An infective larva develops inside the egg but a relatively high temperature is required for rapid growth. In temperate climates, embryonation of T. suis eggs may take more than 1 year. When swallowed by a suitable host, the eggs hatch and develop to mature adults in about 12–20 weeks after infection in lambs and goats and 7 weeks in pigs. The disease in sheep occurs most commonly after hot, dry weather, which effectively cleanses the pasture of other nematode larvae but the resistant Trichuris spp. eggs survive and are ingested when the sheep eat close to the ground to obtain grain given as drought feed.

Diagnosis depends on detection in the feces of the yellow oval eggs, which have a transparent plug at each end. The eggs are heavier than many others and do not always float well in saturated salt (NaCl) solution. An alternative flotation fluid such as zinc sulfate or sugar is more reliable. At necropsy, the adult worms which are 2–5 cm long are easily recognized by their whip-like appearance – the anterior third is much thinner than the handle-like posterior end.

Chemotherapy may give variable results as Trichuris is only distantly related to the usual target species. Most modern broad-spectrum anthelmintic compounds can be used but not all are active against immature forms and repeat dosing may be necessary.

CHABERTIA

Chabertiocrosis of sheep, goats, and cattle is associated with Chabertia ovina a worm 1–2 cm in length, which inhabits the colon and causes a clinical syndrome similar to that of oesophagostomosis. Disease is mainly seen in sheep in colder areas during the winter months. Infestations occur in cattle but are rarely pathogenic. The lifecycle is direct and resembles that of other strongylid worms. Infective larvae are relatively resistant to cold and heavy infestations may occur in mild winters. After ingestion, larvae undergo a period of development in the wall of the small intestine before passing to the cecum and then to the colon. Unlike Oesophagostomum, the larvae do not cause any significant damage. The infection becomes patent in about 7 weeks.

Clinical signs are first seen when immature adults start to attach to the mucosa about 26 d after infection. Soft blood flecked feces with excess mucus are passed. A protein-losing enteropathy occurs with lowered blood albumin and weight loss. Death may occur in heavy infections.

HABRONEMA AND DRASCHIA

These gastric nematodes of the horse are described in "Summer sores in horses".

MACRACANTHORHYNCHUS (THORNY-HEADED WORM)

Macracanthorhynchus hirudinaceus is included in this section for convenience but it is not a nematode. It belongs to a different phylum, the acanthocephalans. These resemble roundworms in appearance but in some ways are more similar to tapeworms as they lack, for example, a digestive tract. The name 'thorny-headed worm' denotes the hook-covered proscopics which they all possess.

M. hirudinaceus infestations in pigs are not usually heavy and cause relatively little loss. The worms have thick bodies...
when a pig eats an infested grub or adult beetle and eggs are passed some 2–3 months later. The female worm is a prolific egg layer and lives in the host for about 1 year.

Heavy infestations cause slow growth or loss of body weight. The head of the worm pushes deeply into the intestinal mucosa and causes nodules that are clearly visible from the serous surface. Occasional deaths may occur due to intestinal perforation. Sedimentation techniques are better than flotation methods for detecting eggs in feces. Treatment is rarely given as the condition is usually only diagnosed at necropsy. Ivermectin given in the feed to provide 0.1 or 0.2 mg/kg for 5 d gives good results. A single dose of doramectin is only partly effective. Control, if necessary, involves suitable disposal of pig manure and avoidance of contact with the intermediate hosts, beetles.

Lungworm infestation

LUNGWORM IN CATTLE

**ETIOLOGY**
The nematode *Dictyocaulus viviparus* (the bovine lungworm).

**Epidemiology** Disease seen mostly in dairy calves; immunity develops relatively quickly but cattle will succumb if exposed to overwhelming numbers of infective larvae while grazing.

**Signs** Coughing, tachypnea, dyspnea.

**Clinical pathology** Characteristic larvae in feces (but not present during all stages of disease); eosinophilia; enzyme-linked immunosorbent assay (ELISA) tests for serum antibodies.

**Lesions** Large volumes of consolidation in diaphragmatic lobes of lung, emphysema, worms up to 8 cm long in bronchi (only in patent phase of disease).

**Diagnostic confirmation** Clinical pathology as above; at necropsy, distribution of lesions in lungs and demonstration of worms in bronchi.

**Treatment** Benzimidazoles and avermectins/mlbemycins are active against all parasitic stages of *D. viviparus*; the latter also have a persistent protective effect; levamisole also used.

**Control** Vaccination; early season anthelmintic prophylactic programs using suitable intraruminal boluses or multiple doses of avermectins/mlbemycins; keep susceptible animals off potentially dangerous pasture.

**LIFECYCLE**
Adult lungworms live in the trachea and bronchi. The females are prolific egg producers and it has been estimated that a single infected calf may contaminate a pasture with 33 million larvae. The eggs are coughed up and swallowed. They hatch in the air passages or alimentary canal and larvae are passed in the feces. These develop in the dung pat through to the infective third stage, which is protected by cuticles retained from both first and second molts. As the ensheathed larvae cannot feed, glycogen granules are stored in the intestinal cells. Moisture is essential for the survival and development of the larvae and a moderate temperature of 18–21°C (65–70°F) permits their full development to the infective state in 3–7 d. Larvae survive best in cool, damp surroundings, especially when the environment is stabilized by the presence of long herbage or free water. Under optimum conditions, larvae may persist for over 1 year. They can overwinter in climates as cold as Canada and Germany. When warmer spring weather arrives, the larvae resume their motility but quickly die once their food stores are depleted.

Transmission occurs when cattle ingest third-stage larvae while grazing. These migrate through the intestinal wall to reach the mesenteric lymph nodes. From here they pass via the lymphatics to the venous bloodstream and through the heart to the lungs, where they break into the alveoli. They migrate up the bronchioles to their predilection site in the larger air passages and start to lay eggs some 3–4 weeks after infestation. Most adult worms succumb to immune expulsion within a few weeks. These events determine the progression of the clinical syndrome and their approximate timing is as follows:

1. Penetration phase (ingestion to arrival of larvae in lung), days 1–7
2. Prepatent phase (larvae in lung), days 7–25
4. Postpatent phase (lungworms disappearing from lung), days 55–70

**EPIDEMIOLOGY**
Bovine parasitic bronchitis is a sporadic and largely unpredictable disease. This is because immunity develops more quickly than is the case with many other nematode infections, but nevertheless can remain incomplete for many weeks and may wane in the absence of reinfection. In most grazing seasons, immunity will develop fast enough to protect calves against the accumulating numbers of infective larvae on the grass. The farmer may not even realize that his land is contaminated. Clinical outbreaks occur when weather patterns, management or other factors result in sudden exposure to a pasture challenge sufficient to overwhelm any immunity that has already developed. In comparison with the gastrointestinal nematodes of cattle, relatively few worms (i.e. a few hundred or thousand) are required to produce clinical signs. Thus, the disease is almost entirely confined to grazing cattle and occurs most frequently in young animals in their first year on grass, although outbreaks are becoming more common in adults. The epidemiology of lungworm disease is largely concerned with factors determining the number of infective larvae on the pasture and the rate at which they accumulate.

Infective *D. viviparus* larvae are relatively inactive and are incapable of traveling more than 5 cm from the dung pat. Factors that disperse the larvae more widely over the pasture include mechanical spread by:
Lungworm infestation

要 withstand lungworm infection. Nevertheless, it is not unusual for severe infestations to be fatal in well-fed calves.

Acute cases have rapid shallow abdominal breathing of sudden onset that may reach a rate of 60–100 breaths/min. There is a frequent bronchial cough, a slight nasal discharge, a temperature of 40–41°C (104–105°F) and a heart rate of 100–120 bpm. The animal is bright and active and will attempt to eat, although respiratory distress often prevents this. Progress of the disease is rapid and within 24 h dyspnea may become very severe, accompanied by mouth breathing with the head and neck outstretched, a violent respiratory heave and grunt, cyanosis and recumbency. On auscultation, lung consolidation is evidenced by loud breath sounds and crackles are heard over the bronchial tree. The cracking of interstitial emphysema commences over the dorsal two-thirds of the lung but is never as evident as in less acute cases. Fever persists until just before death, which usually occurs in 3–14 d and is greatly hastened by exercise or excitement. The case-fatality rate in this form of the disease is high, probably of the order of 75–80%.

Subacute disease is more common in calves than the very acute form. The onset is usually sudden, the temperature is normal or slightly elevated and there is an increase in the rate (60–70 breaths/min) and depth of respiration. An initial grunt is heard in severe cases and expiration may be relatively prolonged. There are frequent paroxysms of coughing. The course of the disease is longer, 3–4 weeks, and auscultation findings vary widely with the duration of the illness and the area of lung involved. In general, there is consolidation and bronchitis ventrally, and marked emphysema dorsally. Affected animals lose weight very quickly and are very susceptible to secondary bacterial bronchopneumonia. The mortality rate is much less than in the acute form but many surviving calves have severely damaged lungs. Consequently, they may remain stunted for long periods and breathing may be labored for several weeks. Some surviving calves may show a sudden exacerbation of dyspnea around 7–8 weeks after the initial onset of disease. In these relapsed cases the prognosis is grave.

Adult dairy cattle are usually immune but sporadic outbreaks do occur due to waning immunity. Mortality is low but morbidity can be high with reduced milk yields causing significant economic loss. Coughing is a constant feature but other clinical signs are variable and may include dyspnea, nasal discharge, and weight loss. Sudden exposure of immune adults to massive challenge can cause severe interstitial pneumonia.
**CLINICAL PATHOLOGY**

The presence of *D. viviparus* larvae in feces confirms lungworm infestation but their absence does not necessarily exclude the possibility of parasitic bronchitis. No larvae will be passed in the early stages of disease when the causal worms are still immature, nor will they be a constant finding when partially immune animals (e.g., dairy cows) succumb to challenge. In general, larvae can be found about 12 days after signs appear, i.e. around 24 days after infestation occurs. They are few in number at first but may become more numerous later.

**Enzyme-linked immunosorbent assay (ELISA) tests** using adult or larval worm antigen to demonstrate exposure to lungworm infection are available in some countries. Care is required with interpretation as antibodies to adult antigen may not be detectable until several weeks after primary challenge and do not correlate with the immune status of the animal. Eosinophilia is a fairly consistent finding but not pathognomonic.

**An alternative method**, if disease is suspected but the lungworms are still in the prepatent stage, is to examine pasture clippings for larvae. This is a laborious procedure because large amounts of herbage (0.5–1kg) must be used and the yield of larvae is low.

**NECROPSY FINDINGS**

Adult *D. viviparus* are up to 8 cm long and easily seen when the trachea and bronchi are cut open. Worms may also be recovered by lung perfusion. Up to several thousand may be present in severely affected animals. In prepatent disease however careful microscopic examination of bronchial mucus is necessary to find larvae. Adult worms may be few or absent if the case is of sufficient duration for immune expulsion to have taken place.

In **acute cases**, morphological changes include:

- Enlargement of the lungs due to edema and emphysema
- Widespread areas of collapsed tissue of a dark pink color
- Hemorrhagic bronchitis with much fluid filling all the air passages
- Enlargement of the regional lymph nodes.

Histologically, the characteristic signs are:

- Edema
- Eosinophilic infiltration
- Dilation of lymphatics
- Filling of the alveoli and bronchi with inflammatory debris

- Larvae in the bronchioles and alveoli.

**In subacute cases**, interstitial emphysema is usually gross. Areas of dark pink consolidation are present in the diaphragmatic lobe and may also occur in other lobes. They can occupy two-thirds of the lung volume. There is froth in the bronchi and trachea. The regional lymph nodes are enlarged. Histologically, eggs and larvae can be seen in the air passages, the bronchial epithelium is much thickened, the bronchioles are obstructed with exudate and the alveoli show epithelialization and foreign-body giant cell reaction.

**The reinfection syndrome** is characterized by the presence of numerous 5 mm gray-green nodules formed by lymphoreticular cells clustering around dead larvae.

**DIAGNOSTIC CONFIRMATION**

*D. viviparus* larvae may be demonstrated by placing feces on a fine sieve or dental gauze on the top of a water-filled funnel (the Baermann technique). The larvae that swim into the water and collect at the bottom of the funnel are less than 0.5 mm long, sluggish and often appear curved or coiled. Their most important diagnostic feature is the presence of easily visible refractile granules in the intestinal cells. As not all animals will be shedding larvae, samples should be taken from all, or at least a representative proportion of the group. Grass samples are washed in water with a surfactant and the sediment Baermannized as above. A technique which effectively separates larvae from plant debris by migration through agar gel has been reported. Gathering grass close to dung pits maximizes chances of finding larvae. Cattle with parasitic bronchitis are likely to have eosinophilia and serological tests can be used to rule out some other respiratory diseases such as infectious bovine rhinotracheitis (IBR).

**In view of the uncertainties** associated with laboratory tests for parasitic bronchitis and the need for prompt treatment, diagnosis often has to be based on clinical history, signs and auscultation. Affected animals have usually grazed alongside potential carriers or had access to pasture previously used by susceptible calves or older carrier animals. The timing of the outbreak may coincide with that expected from recycling of an infection initiated by overwintered larva (often 2–4 months after turnout) or recent exposure to heavily contaminated land. Many of the clinical signs of parasitic bronchitis are common to pneumonias of bacterial and viral origin. One feature which may be of value in differentiation is the relative softness and paroxysmal nature of the cough in parasitic infection.

**DIFFERENTIAL DIAGNOSIS**

- Bacterial bronchopneumonia
- Acute and chronic interstitial pneumonia
- Viral pneumonia
- Acute interstitial pneumonia (fog fever)
- Heavy infestations with ascarid larvae on pastures contaminated with pig feces

In **adult cattle**, the major problem in diagnosis is to differentiate the acute form of the disease from acute interstitial pneumonia due to other causes. Clinically, the diseases are indistinguishable, and a history of movement onto a new pasture within 2–4 months after turnout is common. Therefore a diagnosis may be possible from the history alone.

**TREATMENT**

Anthelmintics may be used prophylactically to prevent disease from occurring, as a curative treatment once disease strikes, or to prevent reinfection following an outbreak. Ivermectins and milbemycins are particularly useful for prophylaxis and prevention of reinfection as they are not only highly effective against the lungworms present in the animals at the time of treatment but have prolonged activity against subsequent incoming larvae. The duration of this persistent effect varies with compound and formulation.

Most modern broad-spectrum drugs are active against *D. viviparus*. Dosage rates and label claims vary from country to country according to local conditions and regulatory requirements. *Avermectins* and *milbemycins* (macrocyclic lactones) are particularly potent against immature and mature stages; doses of ivermectin, for example, as low as 0.05 mg/kg are effective. At commercial dose rates, ivermectin by injection or as a pour-on formulation provides residual protection for up to 28 d; corresponding figures are up to 35 d for doramectin by injection and 42 d both for doramectin as a pour-on formulation and moxidectin by either route of administration. These compounds are given at 0.2 mg/kg by injection and 0.5 mg/kg as a pour-on formulation. Eprinomectin is the compound of choice for adult dairy cattle as it has a nil milk withdrawal period and provides residual protection of up to 28 d when given topically (0.5 mg/kg). Albendazole
There are also pulse release boluses containing oxfendazole which release five larvae. Oxfendazole bolus) or to reach the lungs between pulses (oxfendazole bolus), which may allow immunity to develop.

For veterinarians in the field the outcome of therapeutic treatment is often unpredictable as it depends on the amount of structural damage in the lungs. Best results are obtained early in the course of disease when most pathological changes can be quickly reversed. In severe cases, treatment may initially exacerbate clinical signs as the death and disintegration of many worms in the air passages releases antigens and adds to the mass of foreign material that can be aspirated. Because of animal welfare considerations and the high risk of mortality, anthelmintic treatments are often combined with an antihistamine or non-steroidal anti-inflammatory drug (NSAID) such as flunixin to reduce the severity of the reaction to the larvae and an antibiotic or sulfonamide to prevent secondary bacterial infection. Severely affected animals should be brought indoors for nursing and all other members of the group removed from the contaminated pasture and placed on clean grazing ground.

CONTROL

Two major strategies of control derive from the premise that the main factor governing the occurrence of disease is the density of D. viviparum larvae on pasture grazed by susceptible cattle. Firstly, cattle grazing potentially contaminated pasture can be protected by vaccination or anthelmintic cover. Alternatively, steps can be taken to ensure that pastures are safe for grazing. This is usually achieved by prophylactic anthelmintic programs, but delaying spring turnout until overwintered larvae have died away is a theoretical option on organic farms.15

Sensible grazing management is important in all systems but cannot be relied upon, per se, for controlling parasitic bronchitis in view of the unpredictable nature of the disease. Although natural immunity provides adequate protection on many farms, it cannot be accurately measured or predetermined.16 With the possible exception of beef suckler systems, calves should not be run or follow older cattle as these may harbor asymptomatic patent infections and contaminate the pasture. An important consideration is that clean pasture can be contaminated by larvae from neighboring fields carried on windborne fungal spores (see epidemiology paragraph earlier). Although the numbers of larvae spread in this way are likely to be small, they can initiate the epidemiological cycle culminating in disease after some weeks.

Vaccination of calves with two doses of 1000 infective larvae attenuated by irradiation is a long-established and effective method of preventing disease. Only healthy calves should be vaccinated and they should be at least 8 weeks old. The vaccine is given 6 and 4 weeks prior to turnout. Exposure to lightly contaminated pasture will boost immunity but low-grade patent infections may develop in some animals. Vaccinated and non-vaccinated calves should not be grazed together as the former may contaminate the pasture enabling lungworm to cycle through the susceptible animals. The vaccine gives a high level of protection under most conditions but vaccinated calves should not be put onto heavily contaminated pasture. Coughing may occur when immune responses kill lungworm larvae in the lungs. Overt disease can occur in cases of overwhelming challenge. To avoid such problems on severely affected farms, vaccinated calves should be allowed only gradual access to pasture.

In some endemic areas, for example in the south of Ireland which has mild winters and an early start to the grazing season, the ideal vaccination program described earlier may be inconvenient and it is possible, by cautiously avoiding periods when massive pasture contamination are likely to occur, to vaccinate at pasture. Calves are sometimes vaccinated at less than 8 weeks old to allow spring-born calves to graze during late summer and autumn 17 but optimal protection may not be afforded in all cases.

Strategic anthelmintic programs provide an alternative to vaccination. The aim is to suppress the infection initiated by overwintered larvae and thereby prevent subsequent contamination of the pasture. This can be done by application of a suitable intraruminal bolus at or just before spring turnout or by giving two or three doses of an avermectin/milbemycin during the early grazing season. These systems are designed to control parasitic gastroenteritis as well as lungworm. Clinical field experiments have demonstrated good results with ivermectin, fenbendazole, and oxfendazole boluses and with ivermectin treatments given at 3, 8, and 13 weeks after turnout, or doramectin administered at turnout and again 8 weeks later. Calves may become vulnerable after the period of anthelmintic cover if pasture contamination occurs (e.g. because of fungal spread). An extra anthelmintic treatment may be indicated in regions with a very long grazing season. Calves which are exposed to infection but protected by chemoprophylaxis during their first grazing season generally have substantial resistance to reinfection in their second year.19 Nevertheless, field experiments have shown that immunity can be compromised to a degree related to the level of protection provided.20 There is concern that such intensive treatment may provoke anthelmintic resistance but no resistant strains of D. viviparum have yet been reported.

REFERENCES

**LUNGWORM IN HORSES**

**Etiology** The nematode parasite *Dictyocaulus arnfieldi*.

**Epidemiology** Infection is by ingestion of larvae on herbage; donkeys and foals shed most larvae, but adult horses can perpetuate lifecycle.

**Signs** Chronic cough in adult horses.

**Clinical pathology** Eggs or larvae in feces (often absent in affected adults), eosinophils in tracheal mucus.

**Lesions** Discrete areas of hyperinflation in lung tissue.

**Diagnostic confirmation** Response to treatment if no eggs/larvae in feces.

**Treatment** Ivermectin, fenbendazole (elevated dose), mebendazole over 5 d for donkeys.

**Control** Avoid grazing donkeys and horses on same pasture.

**CLINICAL PATHOLOGY**

Characteristic eggs may be found in the feces of a small proportion of cases. Eosinophils and sometimes eggs or larvae may be demonstrated in tracheal mucus.

**NECROPSY FINDINGS**

The most obvious lesions at necropsy are discrete patches of overinflation.

**DIFFERENTIAL DIAGNOSIS**

- Recurrent airway obstruction (heaves)
- Pulmonary abscessation and pneumonia
- Inflammatory airway disease.

**TREATMENT**

Ivermectin at the standard equine dose is highly effective against immature and mature stages. For donkeys, mebendazole may be used at 15–20 mg/kg daily for 5 d, but this should not be attempted within the first 4 months of pregnancy.

**LUNGWORM IN SHEEP AND GOATS**

**Etiology** The nematode parasites *Dictyocaulus viviparus*, *Muellerius capillaris*, and *Protostrongylus rufescens*.

**Epidemiology** Infective *D. viviparus* larvae are found on grass but *M. capillaris* and *P. rufescens* are transmitted when molluscan intermediate hosts are accidentally ingested by grazing animals.

**Signs** *D. viviparus* and *P. rufescens* can cause bronchitis and loss of condition.

**Clinical pathology** Characteristic larvae in feces.

**Lesions** *D. viviparus* and *P. rufescens*; scattered patches of consolidation, *M. capillaris*: small fibrous nodules up to 5 mm in diameter.

**Diagnostic confirmation** Characteristic larvae in feces.

**Treatment** Ivermectin/milbemycin, benzimidazoles or levamisole.

**Control** No specific measures available.

**DIFFERENTIAL DIAGNOSIS**

- Recurrent airway obstruction (heaves)
- Pulmonary abscessation and pneumonia
- Inflammatory airway disease.

**TREATMENT**

Ivermectin at the standard dose is highly effective against immature and mature stages. For donkeys, mebendazole may be used at 15–20 mg/kg daily for 5 d, but this should not be attempted within the first 4 months of pregnancy.

**ETIOLOGY**

Lungworm disease in horses is associated with the nematode parasite *Dictyocaulus arnfieldi*.

**LIFECYCLE**

The lifecycle of *D. arnfieldi* is direct and is almost identical to that of *D. viviparus* except that the eggs do not hatch until shortly after they are passed in the feces.

**EPIDEMIOLOGY**

Infestations with *D. arnfieldi* are recorded more commonly in donkeys than in horses and the former are considered to be the more normal host. Patent infections may persist in donkeys throughout their lives but in horses are generally confined to foals. These animals therefore provide the most important sources of pasture contamination. Nevertheless, a small proportion of infected adult horses shed low numbers of eggs and this may be sufficient to perpetuate the lifecycle even in the absence of donkeys and foals. As with *D. viviparus*, larvae can cross field boundaries by fungal transfer.

**PATHOGENESIS**

Adult worms are found in the smaller bronchi which they almost completely block.3 In adult horses however, few larvae reaching the lungs develop to this stage. Bronchioloel in affected areas are surrounded by dense infiltrations of inflammatory cells, the epithelium becomes hyperplastic and excessive mucus is produced. The consequent interference with air flow leads to patches of hyperinflation in the lung tissue.

**CLINICAL FINDINGS**

Lungworm disease in horses is characterized by a chronic cough. Experimental infections produce an afebrile condition with coughing, increased respiratory rates and forced expiration being most intense during weeks 3–5 after infection. Thereafter the signs decrease in severity but coughing may persist for several months.2 Heavy infestations in donkeys do not cause clinical illness. Horse foals may also be symptomless although some show clinical signs.

**CLINICAL PATHOLOGY**

Characteristic eggs may be found in the feces of a small proportion of cases. Eosinophils and sometimes eggs or larvae may be demonstrated in tracheal mucus.3

**NECROPSY FINDINGS**

The most obvious lesions at necropsy are discrete patches of overinflation.

**DIFFERENTIAL DIAGNOSIS**

- Recurrent airway obstruction (heaves)
- Pulmonary abscessation and pneumonia
- Inflammatory airway disease.

**TREATMENT**

Ivermectin at the standard equine dose is highly effective against immature and mature stages. For donkeys, mebendazole may be used at 15–20 mg/kg daily for 5 d, but this should not be attempted within the first 4 months of pregnancy.

**REFERENCES**

world and in many temperate areas almost all sheep are infected. Massive invasion with larvae is uncommon because the intermediate hosts are not usually ingested in large numbers nor are they grossly infested with larvae. Massive infestations with this worm do not develop acutely and heavy infestations, when they occur, appear to develop over a long period of time. Infected sheep carry patent infection from one year to the next.

**PATHOGENESIS**
The relative pathogenicity of each lungworm is dependent on its predilection site. *D. filaria* lives in the trachea and bronchi so aspirated eggs, larvae, and debris can affect a large volume of lung tissue. It is therefore the most pathogenic species and provokes changes resembling those described for *D. viviparus*. The volume of damaged lung is however usually insufficient to cause severe dyspnea. Adult *P. rufescens* are found in smaller bronchioles and so associated lesions are much smaller. *M. capillaris* is found in the lung parenchyma where it becomes encysted in fibrous nodules. Lesions are thereby confined to its immediate surroundings. Consequently, this worm is generally considered to be relatively innocuous. Heavy mixed strongylid infections can impair pulmonary gaseous exchange.

**CLINICAL FINDINGS**
Lambs 4–6 months of age are most severely affected with lungworms but sheep of all ages are susceptible. Clinically *D. filaria* is associated with bronchial irritation which results in coughing, moderate dyspnea and loss of condition. There may be added fever and evidence of toxemia if secondary bacterial infection occurs. It is highly pathogenic in young goats. *P. rufescens* infestations in sheep and goats cause clinical signs similar to those of *D. filaria*.

**CLINICAL PATHOLOGY**
Laboratory diagnosis depends upon the detection of first-stage larvae in the feces by the Baermann technique. *D. filaria* larvae have refractile granules in their intestinal cells and a conical tail. *P. rufescens* has a wavy tail as does *M. capillaris* which, in addition, has a spine just anterior to the tail.

**NECROPSY FINDINGS**
*D. filaria* lesions are similar to those of the subacute form of parasitic bronchitis in calves with exudate in the bronchioles and scattered patches of consolidation, but widespread lesions are not common. *M. capillaris* is found in small fibrous nodules up to 5 mm in diameter. Most of these are in the parenchyma of the lung immediately under the pleura. Many of them are calcified and often contain only one live or dead worm. Infestation of goads leads to a diffuse infection quite different to the nodular reaction in sheep and to the production of an interstitial pneumonia. Whether this is due solely to *M. capillaris* infection or whether a chlamydial or viral agent involved has not been determined.

**DIAGNOSTIC CONFIRMATION**
The presence of larvae in the feces confirms lungworm infection but their number is often no indication of the degree of infestation.

**DIFFERENTIAL DIAGNOSIS**
Lungworm infestation in sheep needs to be differentiated from maedi and jaagsiekte.

**TREATMENT**
Ivermectin, moxidectin, the benzimidazoles and levamisole are effective against *D. filaria* at normal dose rates. Ivermectin, in addition, has a label claim for *P. rufescens*. It is doubtful whether treatment of sheep for *M. capillaris* is ever justified. In goats, one or two doses of ivermectin (0.2 mg/kg) or elevated doses of benzimidazoles destroys the adult worms but not the immature stage, but regular doses of fenbendazole (up to 5.0 mg/kg/d) in the feed for 1–2 weeks or albendazole (1.0 mg/kg for 2 weeks) are highly effective against all stages.

**CONTROL**
An attenuated vaccine for *D. filaria* is available in a few countries where this worm is a particular problem. With most forms of sheep husbandry, there are few precautionary measures that can be taken, particularly against lungworms with molluscan intermediate hosts.

**REFERENCES**

**EPIZOOTIOLOGY**
The disease is most prevalent in pigs 4–6 months of age in husbandry systems that allow access to earthworms. The eggs first appear in the feces 3–4 weeks after infestation and at their peak reach levels of 25–50 epg. The eggs are very resistant to cold temperatures and can survive for over 1 year in the soil. Larvae may survive in the earthworm for up to 7 years. The primary host must ingest an intermediate host to become infected and this is an important factor influencing the spread of the disease. Once ingested the infective larvae migrate to the lungs in much the same manner as do *D. viviparus* larvae. Many infestations are asymptomatic and induce immunity against re-infection.

**PATHOGENESIS**
The pathogenesis is similar to that of *D. viviparus*. These worms may provide a route of transmission for swine influenza virus, and possibly hog cholera virus, from pig to pig, but this is unproven.

**CLINICAL FINDINGS**
Lungworm infection in pigs can cause a marked check in growth rate. The bronchitis is accompanied by sporadic bouts of a barking cough, which is easily stimulated by exercise. Pneumonia is a feature of severe cases.

**CLINICAL PATHOLOGY**
Laboratory diagnosis is by demonstration of the characteristic eggs in feces.
**NECROPSY FINDINGS**

Early lesions comprise small areas of consolidation due to verminous pneumonia. More chronic cases have bronchitis, emphysema, peribronchial lymphoid hyperplasia and bronchiolar muscular hypertrophy, often accompanied by areas of overinflation. The lesions are small and discrete, appearing as grayish nodules up to 1 cm in diameter and are present particularly at the ventral border of the diaphragmatic lobes.

**DIAGNOSTIC CONFIRMATION**

The *Metastrongylus* egg is embryonated (larvated), has a thick shell and a wavy outline. They may be missed on routine screening as they are usually passed in small numbers and do not float well in saturated salt (NaCl) solution. A flotation fluid with a higher specific gravity should be used. There will always be a history of access to yards or paddocks where earthworms exist.

**DIFFERENTIAL DIAGNOSIS**

- Other swine pneumonias
- Migrating larvae in heavy Ascaris infestation.

**TREATMENT**

A number of anthelmintics are effective at normal pig dose rates including doramectin, ivermectin, fenbendazole, and flubendazole. Levamisole (8 mg/kg) has been used in the water or feed.

**CONTROL**

Rearing pigs on concrete reduces the risk considerably but, in view of the longevity of the eggs and larvae in the earthworm, little can be done if pigs are kept on contaminated land. Pastures which are known to be contaminated should be left for at least 6 months before restocking, although infested earthworms may persist in hog lots for up to 4 years.

**REVIEW LITERATURE**

**REFERENCE**

**Kidney worm disease in pigs**

**ETIOLOGY**

Stephanurusiosis is a disease of swine caused by the migration of larvae and young adults of the nematode parasite *Stephanurus dentatus* through the body.

**LIFE CYCLE**

*S. dentatus* are large (2–5 cm) thick roundworms which inhabit the perirenal tissues, and less commonly the other abdominal organs and spinal canal of the pig. Adult worms lie in cysts around the renal pelvis and the wall of the ureter. The cysts communicate with the urinary passages and the eggs are passed out into the urine of the host. They are very prolific egg layers and an infective adult sow may yield as many as a million eggs in a day. Under suitable environmental conditions the eggs hatch and, after undergoing two molts, the larvae develop to the infective third stage in about 4 d. The eggs and larvae are very sensitive to cold and desiccation; eggs in a dry situation die overnight. Exposure to temperatures below 10°C (50°F) is damaging and 4°C (40°F) is lethal. Most larvae in optimum conditions of moisture, warmth, and shelter from sunlight survive for about 3 months, some for as long as 5 months. Larvae may survive for long periods as facultative parasites in earthworms and this may enable the larvae to survive even when the soil microclimate is adverse.

**Larvae may penetrate the skin** or be ingested. Larvae that are ingested cross the wall of the stomach, or more commonly the small intestine, and reach the liver via the portal vessels; from the skin the larvae reach the systemic circulation and pass to the liver via the lungs in 1-6 weeks. In the liver the larvae migrate from the blood vessels through the parenchyma and eventually, about 3 months after infestation, having undergone a fourth molt, penetrate the capsule of the liver and reach the perirenal tissues to establish themselves as adults. Egg laying usually commences about 6 months after infestation but the prepatent period may be very much longer and individual worms appear to live as long as 2 years.

**During their migration** the larvae often follow an erratic path and cause the development of atypical lesions and clinical signs. These larvae often reach maturity in these aberrant sites and prenatal infection can occur in this way.

**EPIDEMIOLOGY**

Kidney worms occur commonly in most tropical and subtropical countries such as Africa, the East and West Indies, Brazil, Hawaii, Philippines, the southern United States, and Australia, where the climate is sufficiently mild to permit the survival of eggs and larvae.

**PATHOGENESIS**

The principal effect of these worms is the damage caused by the migrating larvae and young adults. The migrating worms cause a great deal of necrosis, fibrosis, and occasional abscess formation along the path of their migration and this is most marked in the perirenal tissues and the liver. *S. dentatus* have been observed rarely in cattle. Experimentally dosed calves develop severe hepatic injury similar to that which occurs in pigs but the lifecycle is not completed and no perirenal lesions develop.

**CLINICAL FINDINGS**

The mortality rate is not high; production losses and condemnation of parts or all of the infested carcass are of greatest economic significance. Poor growth in spite of a good appetite may be the only sign in mild cases. Badly affected animals become emaciated and develop ascites. In the early stages, nodules in the skin of the belly wall and enlargement and soreness of the peripheral lymph nodes may be evident. Many apparently unrelated clinical signs are produced by aberrant larvae. For example, thrombi may be induced in blood vessels such as the portal veins, hepatic artery and posterior vena cava, while paralysis may result if larvae invade the spinal cord. Involvement of the psoas muscles, causes local pain and stiffness of gait. The passage of larvae through the peritoneum and pleura gives rise to adhesions. Larvae may also become encysted in the lung. Weakness and eventual paralysis of the hindlegs occur in a number of cases. Passage through the peritoneum and pleura causes the formation of adhesions and many larvae become encysted in the lung.

**CLINICAL PATHOLOGY**

Large, thin-walled, embryonated eggs are present in the urine when adult worms
are present in the ureter wall. An eosinophilia is seen 2–3 weeks after infection, peaking at 6–7 weeks and still elevated at 20 weeks. However, this has little specific diagnostic significance. Anemia does not occur. Only a transient rise in aspartate aminotransferase is seen and serum enzymes seem to be of little value in diagnosis.5

**Necropsy Findings**
The common findings include: fibrosis and abscess formation in perirenal tissues with large adult worms present here and occasionally in the pelvis of the kidney and ureter, infects and scars in the kidney and enlargement and scarring of the liver, sometimes accompanied by ascites. The hepatic lesions include irregular whitish tracks in the parenchyma, extensive fibrosis, hemorrhage and eosinophilic abscess formation. The liver may be covered with a diphtheritic membrane. Larvae may also be present in peripheral lymph nodes and cutaneous nodules, in small abscesses in the lung and pancreas and in thrombi of blood vessels, particularly in the liver and lungs. Pleurisy and peritonitis if they are present are usually manifested by adhesions.

**Diagnosis Confirmation**
A definite diagnosis of stephanurosisis may be made by finding eggs in the urine or by necropsy. Young pigs with a heavy infestation of larvae may present a problem in diagnosis because adult worms and characteristic renal lesions may not yet be present. An ELISA test can detect infection from 2 weeks after infection, but serological tests are not likely to become a routine diagnostic procedure.

**Differential Diagnosis**
- Other causes of poor growth and emaciation in pigs, e.g. poor nutrition and chronic bacterial diseases such as necrotic enteritis and swine dysentery, but these are accompanied by intermittent diarrhea
- Other parasitic diseases such as ascariosis and hystronylosis
- Other causes of posterior weakness in pigs such as vitamin A deficiency, osteodystrophy, sometimes fracture of a lumbar vertebral, brucellosis, erysipelas when intervertebral joints are involved, or by spinal cord abscess or lymphoma.

**Treatment**
Single doses of ivermectin or doramectin at 0.3 mg/kg, or fenbendazole at 3 mg/kg in the feed for 3 d are effective against migrating and adult stages, while levamisole at 8 mg/kg removes the adults only but thereby prevents egg output for at least 4 weeks.7

**Control**
Regular anthelmintic treatment of all pigs with fenbendazole or ivermectin at 4-month intervals should prevent further contamination of the environment with eggs. The free-living stages should then eventually die out, but this may take some time as infected earthworms may survive for at least 1 year.

Management techniques may also be used for controlling kidney worm. As the prepatent period of *S. dentatus* is at least 6 months, one method is to breed entirely from gilts until the transmission cycle is broken.10 Under this system the gilts are raised, allowed to farrow and sent to market as soon as the litter is weaned and before any eggs are shed. Boars are confined on concrete to prevent contamination of the soil by eggs in their urine. This technique has the advantage of maintaining a fully stocked farm while control is being achieved but has obvious economic penalties.

Other management techniques depend on the provision of dry ground where eggs and larvae are less likely to survive. Sleeping shelters should be placed on high ground, preferably bare of vegetation. Because pigs in yards commonly urinate against fences, a 2–3 m strip of earth inside the boundary should be kept free of herbage. Muddy spots and water holes should be filled in and drainage provided. Water and feed troughs should be on a concrete apron. Young animals should be segregated from adults and fields rested for 3–6 months after the adults are removed. Such programs are rewarding if carried out diligently and intelligently, but the extra work involved has militated against general acceptance of this approach. Because of the importance of mature animals as sources of infestation, early replacement of breeding stock is recommended in problem herds.

**Nematode induced skin conditions**

**Summer Sores in Horses**

**Etiology**
The various forms of cutaneous habronemosis, with local names such as 'summer sores', 'swamp cancer', and 'bursattee', involve three nematode species, *Habronema muscae*, *H. majus* (syn. *H. microstoma*), and *Draschia megastoma*, the adults of which infest the stomach of horses.

**Lifecyle**
*Habronema* spp. adults are larger (1–2.5 cm long) than those of *D. megastoma* (1.25 cm). The life cycles are indirect; all species use flies as their intermediate hosts. *H. muscae* and *D. megastoma* mainly use the house fly (*Musca domestica*) but can use other muscid species, while *H. majus* usually passes through the stable fly (*Stomoxys calcitrans*), although *Haematobia irritans exigua*, *Sarcophaga melanura*, and the house fly can also be used. The thin-walled larvated eggs hatch in the manure and are ingested by maggots in which they develop. The infective form is reached about the time the adult fly emerges from the puparium. Horses become infected by swallowing dead flies with feed or water or, alternatively, infective larvae may pass through the proboscis of the fly when it is feeding on the lips or on wounds. Larvae that are swallowed reach maturity in the stomach while those deposited in wounds cause cutaneous habronemosis. Stray larvae may be found anywhere throughout the body but
EPIDEMIOLOGY

*Habronema* and *Draschia* have a worldwide distribution. They are of importance only in warmer climates, where they are commonly found, especially in wetter areas where the intermediate hosts are common. Elsewhere they tend to be a sporadic nuisance. Gastric granulomas and most cutaneous lesions appear to be associated with *D. megastoma*, although typical cutaneous lesions do occur naturally and have been produced experimentally by the cutaneous implantation of *H. muscae* larvae. The latter however only cause a transitory reaction. Horses of all ages are susceptible but the disease is most common in adults.

PATHOGENESIS

Two types of gastric habronemosis occur. The more serious is associated with *D. megastoma*. Larvae invade the gastric mucosa and cause the development of large granulomatous masses which later penetrate the stomach glands and cause a catarrhal gastritis with the production of a thick tenacious mucus. Heavy burdens may cause ulceration.

In cutaneous and conjunctival habronemosis, *Habronema* spp. larvae deposited in wounds cause local inflammation and the development of extensive granulation tissue. Secondary bacterial or mycotic invasions may occur. In the eye, similar lesions form on the inner canthus, the nictitating membrane or the eyelid. These can cause profuse lacrimation and other signs of local irritation.

CLINICAL FINDINGS

Gastric habronemosis does not usually provoke clinical signs, but affected animals may, on occasion, have a poor coat and a variable appetite. Large tumors may cause pyloric obstruction and gastric distension. When perforation occurs there is depression, a fever of 39.5–40.5°C (103–105°F) and pain and heat on the left side just behind the costal arch. Mild-to-moderate colic may be evidenced when intestinal stenosis is present. If the spleen is involved there is marked anemia and a gross increase in the total leukocyte count with a shift to the left.

Cutaneous habronemosis is manifested by the appearance of lesions on those parts of the body where skin wounds or excoriations are most likely to occur and where the horse cannot easily displace the vector flies. Thus they are most common on the face below the malar canthus of the eye and on the midline of the abdomen, extending in males onto the prepuce and penis. Less commonly, lesions may be found on the legs and withers but those occurring in the region of the fetlocks and coronary band are especially serious. The cutaneous lesions commence as small papules with eroded, scab-covered centers. Development is rapid and individual lesions may increase to 30 cm in diameter in a few months. The center is depressed and composed of coarse, red granulation tissue covered with a grayish necrotic membrane and the edges are raised and thickened. Although the lesions do not usually heal spontaneously, they may regress in colder weather and recur the following summer. There is little discharge. The sores are unsightly, inconvenient and cause some irritation.

In conjunctival habronemosis lesions on the nictitating membrane may be as large as 5 mm in diameter. The conjunctivitis is manifested by small, yellow, necrotic masses about 1 mm in diameter, accompanied by soreness and laceration, which do not respond to standard treatments for bacterial conjunctivitis.

CLINICAL PATHOLOGY

Diagnosis is difficult in the gastric form of the disease because the eggs and larvae are not easy to find in the feces. Biopsy of a cutaneous lesion reveals connective tissue containing small, yellow caseous areas up to 5 mm in diameter. Larvae may be found in skin scrapings or biopsies and ocular lesions can be found in the conjunctival sac or discharges. A marked local eosinophilia occurs.

NECROPSY FINDINGS

Tumor-like lesions of *D. megastoma* bulge into the lumen of the stomach and may reach the size of a golf ball. Adult *Habronema* are stout worms but their presence is often masked by a thick tenacious layer of mucus. This is on the glandular part of the stomach and often close to the margo plicatus.

Granulomatous lesions may be found in all the sites mentioned in the description of clinical signs, and although varying in size are of essentially the same composition as described under biopsy earlier. Horses which have had the cutaneous form of the disease may have small nodules in the parenchyma of the lung. These are hard, yellowish and contain ininspissated pus and larvae.

DIAGNOSTIC CONFIRMATION

A biopsy will confirm clinical diagnosis of the cutaneous and conjunctival forms of the condition. Molecular techniques are being developed for detection and specific identification of parasite DNA in feces and biopsies.

DIFFERENTIAL DIAGNOSIS

The gastric form of habronemosis is difficult to differentiate from infestation with stomach bot (*Gasterophilus* larvae or *Trichostrongylus axei*). These parasites often co-exist in the same animal. Cutaneous habronemosis must be distinguished from:

- Fungal granulomata associated with *Hyphomycetes destruens*
- Overgrowth of granulation tissue following a wound
- Equine sarcoids.

TREATMENT

Few anthelmintics have been adequately tested against *Habronema* spp. and *D. megastoma*. Ivermectin 0.2 mg/kg will remove these species from the stomach with a single treatment but a second dose is sometimes necessary to promote healing in cutaneous lesions. Moxidectin (0.4) is active against adult *Habronema muscae*. Fenbendazole used at 10 mg/kg for 5 d is reported to have high efficiency against *D. megastoma* and possibly *Habronema* spp.

CONTROL

Interuption of the lifecycle by careful disposal of horse manure and control of the fly population are obvious measures. In enzootic areas all skin wounds and excoriations should be treated promptly to promote healing and protect them against flies.

REFERENCES

RHABDITID DERMATITIS

*Pelodera* is a sub-genus of the soil nematode *Rhabditis*. Dermatitis associated with the larvae of *P. strongyloides* is rare. It is recorded most commonly in the dog but outbreaks have been observed in cattle, sheep and horses. It has also been an incidental finding in other skin diseases associated with poor husbandry practices. Alopecia is marked, particularly on the neck and flanks. In moderate cases the skin on affected areas is thickened,
wrinkled and scurfy and some pustules are present on the ventral abdomen andudder.\(^2\) Pustules are up to 1 cm in diameter and contain thick, yellow caseous material and worms. There is marked irritation and, in severe cases, affected areas are swollen, raw and exude serum.

*Pelodera strongyloides* is a free-living soil nematode found particularly in decaying leaf mould and similar material. When warm blooded animals lie on its habitat for prolonged periods it takes the opportunity to invade the skin. Thus, infestation is encouraged by housing animals on warm, wet bedding. Under favorable conditions the disease may spread rapidly.\(^3\) In these circumstances the lesions occur most commonly where the skin contacts the bedding. The nematodes are easily detected in skin scrapings or biopsy specimens, and in samples of the bedding, preferably taken from the top few centimeters in the pen.

**Control measures** include the regular removal of soiled bedding and steps to ensure that the litter is kept dry. Spontaneous recovery usually occurs if these precautions are taken but local application of a parasiticide and symptomatic therapy will speed recovery.

### ONCHOCERCOSIS

*Onchocerca* spp. are filamentous, thread-like nematodes found mostly as convoluted masses in fibrous tissues. They vary in length; those of the horse are 15-18 cm long, while bovine species may be as long as 75 cm. They are filariform worms and the females produce motile embryos (microfilariae). These congregate in the skin and subcutaneous tissues at the favored feeding site of their intermediate host. Each Onchocerca species uses a particular biting fly, usually a species of *Culicoides* (midge) or *Simulium* (blackfly). Transmission takes place when infective larvae that develop in the fly are deposited on the skin of their host at a subsequent feed.

Infestation by adult worms is often symptomless and prevalence tends to increase with age. Relatively non-pathogenic species of widespread occurrence in cattle include *O. gutturosa* in the ligamentum nuchae and *O. lienalis* in the gastroplenic ligament, while horses often harbor *O. cervicalis* in the ligamentum nuchae and *O. reticulata* around the flexor tendons. Some cause rejection of meat for human consumption. *O. gibsoni* in Australian cattle, for example, provokes nodules up to 3 cm across in subcutaneous tissues, especially in the brisket. *O. ochengi* produces subcutaneous nodules in African cattle, most commonly on the scrotum and udder. Other species may be more pathogenic such as *O. armillata*, which lives in the aorta of cattle, buffalo and goats in India and Iran.\(^1\)

**Losses caused by adult worms** are slight although *O. gibsoni* in cattle causes unsightly lesions and rejection of beef carcases from the high-class meat trade. The characteristic nodules of *O. gibsoni* are usually freely movable and consist of fibrous tissue canalized by the long body of the worms. With *O. armillata*, the inner wall of the aorta may be corrugated and swollen. In horses, new infections with *O. reticulata* may cause swelling of the suspensory ligament and a hot edematous swelling of the posterior part of the cannon which persists for 3-4 weeks. After the swelling subsides, the suspensory ligament remains thickened and small caseated or calcified nodules may be palpated. Affected animals are lame while the area is edematous and swollen, but many recover when the swelling disappears. *O. cervicalis* causes fibrotic, caseous and calcified lesions in the ligamentum nuchae but clinical signs are not seen. The conditions known as 'pox evil' and 'fistulous withers' are no longer thought to be associated with this parasite.

**Microfilariae** may sometimes be damaging. Those of *O. cervicalis*, for example, are occasionally observed in the cornea of horses but the proposed causal relationship with periodic ophthalmitis is no longer thought to be valid. They can however induce hypersensitivity reactions in the skin of some individuals. Lesions are characterized by alopecia, scaliness and pruritus, particularly along the ventral abdomen. They may extend between the forelegs and backlegs to include the thigh, and in severe cases they may extend up the lower abdominal wall. Some horses have lesions on the face, neck, or thorax.\(^2\) The lesions may be confused with those associated with hornfly feeding but these are more likely to include crusting and ulcerating demantias.\(^3\) In onchocercosis, microfilariae are not detectable in the bloodstream but may be found in skin biopsies. *O. ochengi* in African cattle has been associated with a dermatitis resembling demodectic mange and pox,\(^4\) while in Turkey microfilariae of *O. gutturosa*, *O. lienalis*, and an unidentified species have recently been reported in association with teat lesions including sores, chaps, and nodules.\(^5\)

**Control** of the intermediate hosts is virtually impossible but valuable horses prone to hypersensitivity to *O. cervicalis* microfilariae can be partially protected by housing at night as most *Culicoides* species feed during twilight hours and/or at night. The use of insect repellents and avoidance, if possible, of grazing areas where the insects are likely to be in large numbers will also be beneficial. There is no specific treatment for the adult worms. A novel approach has been the experimental use of tetracycline to eliminate *O. ochengi* by killing the symbiotic bacterium *Wolbachia* which is found in many, but not all, filarial species.\(^6\) Ivermectin 0.2 mg/kg\(^2\) or moxidectin 0.4 mg/kg\(^2\) can be used to eliminate microfilariae in horses. About 10% of treated horses develop an edematous reaction within 24 h.\(^7\) This is usually restricted to the area of the lesion but some may develop a pruritic ventral edema.

### ELAEOPHOROSIS (FILARIAL DERMATITIS) IN SHEEP

*Elaeophora* spp. are filarial nematodes that inhabit blood vessels. Relatively non-pathogenic species include *E. bohmi*, which has been reported in horses in Austria and *E. poeli*, which occurs in cattle in Africa and Asia. Of greater clinical significance is *E. schneideri*, which is primarily a parasite of mule deer in North America. Elk, white-tailed deer, and moose may act as reservoir hosts.\(^1\) This species causes chronic disease in adult sheep grazing at high altitudes during the summer months. Horse flies such as *Hybomitra* and *Tabanus* spp. are intermediate hosts.\(^2\) In sheep, larvae develop in the first leptomeningeal arteries for 3-5 weeks after which they migrate into the common carotid and internal maxillary arteries, although they may also be found in other arteries. The adults grow to 120 mm in length and mature in about 5 months.\(^3\)

**ELAEOPHOROSIS** usually produces no detectable effects in the natural host, the mule deer. Clinical signs in abnormal hosts attributable to migrating worms are thought to be the result of the prolonged sojourn of the larvae in smaller blood vessels. This reduces blood flow and may result in blindness, deafness, and circling.
PARAFILARIAOSIS

Horses in Europe, particularly eastern Europe, China, South America, and North Africa, are sometimes infected with *Parafilaria multivulminosa*, a 3–6 cm long nematode. The female lives in a nodule in the skin which it pierces to lay eggs on the surface. The subcutaneous nodules ulcerate, bleed, heal, and disappear spontaneously. The hemorrhagic exudate from the lesion attracts bloodsucking flies such as *Haematobia*, which ingest the eggs and act as the intermediate host. The condition is relatively benign, occurring in the spring, summer, and autumn. Many nodules may occur on a horse but although unsightly they do little harm unless they interfere with harness straps.

Similar lesions in cattle are associated with *P. bovicola*, which is endemic in eastern and some western European countries, India, the Philippines, Japan, and South Africa. It has recently become established in Canada, Ireland, and Sweden, where it spread at a rate of 50 km/year. Muscids flies, for example *Musca autumnalis* in Sweden, act as the intermediate host and the prepatent period in cattle is 7–10 months. The condition is seen mostly in late winter, spring, and summer and causes widespread economic losses due to carcass trimming and hide damage. The majority of lesions are superficial and localized but sometimes they cover the whole carcass. In such cases intermural lesions will be found within the fascia of adjacent muscles. Subperiosteal, abdominal, subpleural, and thoracic lesions may also occur and cause condemnation of the whole carcass. *Suifilaria suis* causes similar lesions in the pig in South Africa.

Clinical signs are restricted to the presence of bleeder points and a diagnosis may be made by examining a smear of the exudate microscopically for larvated eggs. Ivermectin markedly reduces the area of the lesions and the mass of affected tissue. A control program for *P. bovicola* using ivermectin has been evaluated. Blood spots were dramatically reduced but transmission was not stopped. Nitroxynil 20 mg/kg twice at 72-hour intervals is effective in reducing the number and area of lesions but care must be taken to ensure accuracy of dosing or toxic signs of drug overdose may be seen. Topical levamisole may also be effective.

**REFERENCES**

**STEPHANOFILARIAOSIS**

*Stephanofilaria* spp. are very small (up to 8 mm) filarial nematodes living in cysts at the base of hair follicles. They are associated with subcutaneous tissue lesions in cattle and buffalo. There are a number of species including *S. dedoesi* (synonym *S. assamensis*, *S. kaeli*, and *S. okinawaensis*), which provokes a dermatitis (‘cascado’) affecting the eyes, neck, withers, shoulders and dewlap in parts of Asia as well as ‘humpsore’ in India, leg sores on cattle in Malaysia and muzzle and teat lesions in Japan. *S. zearei* causes ‘earsore’ in India and *S. stilesi* is responsible for dermatitis of the ventral abdomen in parts of the United States and Russia. A similar species in Queensland, Australia affects the head, neck, dewlap, and sternum. *S. boomkeri* has recently been described in pigs in Africa. The adult worms release microfilariae which later develop in flies that feed on the sores. The vector for *S. dedoesi* is *Musca conducens*, while the orn fly *Haematobia irritans* is intermediate host for *S. stilesi* in the United States. The Australian species is probably spread by the buffalo fly, *Haematobia irritans exigua*.

Cutaneous stephanofilariosis starts with small papules which later coalesce to produce lesions varying from 3 to 15 cm in diameter. They are an extreme irritant and evidence of rubbing is present. Part but not all of the hair is lost and dried exudate forms a thick, crumbly scab which may crack to expose blood-stained fluid. Skin scrapings taken from beneath the scab may reveal worm fragments. If healing occurs, the scab disappears leaving a scar. Infection does not affect growth rate, and treatment and control is required only in stud cattle where lesions are esthetically undesirable. Ivermectin is an effective microfilaricide in buffaloes and reduces the number of adult worms. Oral levamisole 8 mg/kg once or twice at 3 to 4-week intervals is reported to be effective.7 Ointments containing insecticides may aid control. The Asian species require a pre-existing wound for infection to take place. Simple wound prevention and treatment would therefore reduce the risk of disease in this region.

**REFERENCES**

**DIFFERENTIAL DIAGNOSIS**

- The distribution of lesions and pruritis help to distinguish elaeophorosis from:
  - contagious ecthyma
  - mycotic dermatitis
  - strawberry foot rot.
- Photosensitization lesions may have a very similar distribution and appearance to those caused by the elaeophorous *filaria* but there is usually marked edema and swelling and a history of access to photosensitizing or hepatotoxic plants.

Microfilariae may be detected in skin biopsies but skin scrapings and blood examinations are not satisfactory. The number of microfilariae in the skin of sheep is always low and negative results may be obtained in known positive sheep.

**TREATMENT** with piperazine (220 mg/kg) has been suggested. Unfortunately the death of adult parasites in heavily infected sheep may cause the death of the host, presumably by blocking branches of the carotid arteries. Information is lacking on the activity of modern drugs on this infection.

Nematodes affecting eyes or nervous system

THELAZIA (EYEWORM)

A number of species of the nematode genus Thelazia occur in the conjunctival sac and tear ducts of mammals throughout the world. T. gulosa and T. skrjabini are the main species in cattle in the New World while T. rhodesi is the commonest in the Old World and T. lacrymalis is cosmopolitan in horses. They are thin worms up to 2 cm long. Infestation is often inapparent but they may cause excessive lacrimation, photophobia, conjunctivitis, keratitis, corneal ulceration, and abscess formation on the eyelids.1-3 In horses, this condition mainly occurs in young animals. One survey in Kentucky, in the United States, found 43% of horses up to 4 years old to be infected.4 In those species that have been studied, the life cycles are indirect with muscid flies, particularly the face fly Musca autumnalis,5 being the intermediate hosts. These flies deposit larvae on the conjunctiva when feeding on fluid around the eye. The disease is mainly seen in summer and autumn when the flies are active. It is usually more common in cattle than horses5 and worms may be more abundant in beef than in dairy cattle.6 Eyeworm in cattle is differentiated from infectious keratitis by observing the adult worm in the conjunctival sac or demonstrating first-stage larvae in eye washings. Ivermectin and doramectin are active against the adult worm in cattle7-8 but anecdotal reports suggest that it may be less effective in horses.

ELAPHOSTRONGYLOUS

Elaphostrongylus papillosa (H. delatix; Microrema delatix) is a small nematode which has been found in horses on rare occasions. Like Pelodera, it is a free-living saprobiotic organism that has the ability to become an opportunistic parasite. H. papillosa however invades the deeper tissues where it reproduces. Enormous numbers may be seen in granulomatous lesions that grow to several cm in diameter. Lesions may be found near the eye, in the prepuce, nares or the maxilla. The latter may be sufficiently large to cause the hard palate to bulge, displacing the molars and causing difficulty in mastication.1 Putative hematogenous spread gives rise to similar lesions in the kidney which may be misdiagnosed as renal neoplasia. The worm also invades the brain and spinal cord2 but here the lesions are usually microscopic and consist of discrete granulomata with a vascular orientation. Affected horses may show a wide variety of clinical signs including lethargy, ataxia, and incoordination leading to recumbency and death.3 Diagnosis of superficial lesions is by demonstration of worms and larvae in biopsy samples, but more often H. gingoal is infection is identified retrospectively in histological sections following necropsy.5 The worms are 250-430µm long, have a characteristic bilobed pharynx and often contain a single large egg. This infection must be considered in the differential diagnosis of equine cerebrospinal nematodosis.3,4 Treatment with ivermectin at the maximum safe dose has been attempted although the susceptibility of the worm to this compound is uncertain.

SETARIA

Setaria spp. are long (5-10 cm) thread-like filarial nematodes commonly found in the peritoneal cavity of most domestic animals. S. labiato-papillosa is a cosmopolitan parasite of cattle while S. digitata and the closely related, and perhaps synonymous, species S. marshalli occur only in Asia.

The lifecycle is complete when infected molluscs are ingested by deer and the larvae penetrate the abomasum, migrate, possibly along spinal nerves, to the spinal cord where they develop into adults and migrate into the subarachnoid space.1

Clinical signs are not seen in infected deer, but in sheep and goats the worm continually moves through nervous system tissue causing limping and incoordination followed by almost complete paralysis of the hind limbs or of the neck, body, and all four legs.1-3 There are no signs of cerebral involvement and affected animals remain bright and continue to eat. If given supportive treatment they may survive for at least 1 month. F. tetani also transmits to moose and is responsible for the nervous signs in ‘moose sickness’, including:

- Weakness
- Incoordination
- Circling
- Impaired vision
- Blindness
- Abnormal carriage of the head
- Paralysis
- Lack of fear of man
- Aggressiveness.

No reliable treatment is available for CSE. Ivermectin has no effect on the adult worms, possibly because the large molecules of this compound cannot pass the blood–brain barrier.5 One clinical report describes the treatment of 17 light to moderately affected goats with an NSAID (flunixin meglumine) together with ivermectin and fenbendazole for 5 days.6 Complete recovery occurred in three, partial recovery in eight, but euthanasia was necessary for the remainder.

REVIEW LITERATURE

REFERENCES

S. equina is found worldwide in horses. Adult females produce motile embryos (microfilariae) which circulate in the peripheral blood of the infected animal and are taken up when mosquitoes infect. Larvae develop in the intermediate host and are released when the mosquito subsequently feeds. S. labiato-papillosa reaches maturity in cattle in 8–10 months. Despite their presence, the presence of these worms in the abdominal cavity causes no significant clinical effect.

Serious disease may result if S. labiato-papillosa or S. digitata infect animals other than their own natural host, especially horses, sheep, goats, and humans. In these hosts, they migrate in an abnormal manner causing epizootic cerebrospinal nematodiosis (with local names including Lumbar Paralysis and Kumri) when they invade the brain and spinal cord. Juvenile S. digitata may also invade the eye. Although Setaria is found in cattle in many countries, cerebrospinal nematodiosis is largely restricted to Israel, Japan, China, Korea, India, and Sri Lanka. The incidence is increasing in Taiwan1 and a single case has been reported from the United States.2 Ocular filariosis is seen most commonly in Japan. These are diseases of the summer and autumn when the vectors are most prevalent. The cerebrospinal form sometimes occurs in epidemic proportions, causing deaths in horses, sheep, and goats.

Cerebrospinal nematodiosis may be rapid in onset with affected animals dying within a few days or it may occur gradually over a few days. There may be acute or subacute paralytic weakness and incoordination or paralysis involving the hindlegs most commonly, but sometimes all four legs. Recovery is only partial in many animals but others show only a mild neurological disorder, which gradually becomes indiscernible. There are no systemic signs and the animals may continue to eat. Other diseases causing similar clinical signs include enzootic equine ataxia in horses and paralytic rabies in sheep and goats as lesions due to traumatic injury, spinal cord abscess, warble fly larvae, Strongylus vulgaris, or Halicephalobus gingivalis.

At necropsy, there are no macroscopic changes and sections need to be taken from many levels of the spinal cord to find histological lesions. Focal areas of malacia or microcavitation are seen and in adjacent sites there may be loss of myelin, axonal swelling, degeneration and gitter cell formation.2 Migratory pathways are indicated by necrotic tracts. Where nervous signs have been present for only a few days, a worm or worm fragments may occasionally be found. Molecular techniques have been developed for identifying the responsible species.3 Anthelmintics will not resolve existing lesions but may prevent further damage. Little has been published on treatment or control. Ivermectin gave moderate efficacy (80–88%) against adult S. equina in ponies.4 In a field study, none of 221 goats and sheep injected twice with ivermectin at a dose of 0.2 mg/kg developed setarosis, while 17 of 303 non-injected animals suffered from the disease.5

Hepatic diseases associated with trematodes

FASCIOLIASIS (LIVER FLUKE DISEASE)

Synopsis

Etiology Fasciola hepatica and, in warmer climates, F. gigantica.
Epidemiology Infection by ingestion of metacercariae on herbage; geographical distribution, seasonality and disease risk determined by occurrence of intermediate hosts (lymnaeid mud snails).
Signs Acute syndrome (sheep): sudden death; chronic syndrome (sheep and cattle): weight loss, reduced milk yield, pallor, submandibular edema.
Clinical pathology Acute syndrome: raised serum glutamate dehydrogenase concentrations, anemia; chronic syndrome: characteristic eggs in feces, anemia, hypalbuminemia, raised serum gamma-glutamyl transpeptidase concentrations.
Lesions Acute syndrome: pale friable liver with parasitic tracts and hemorrhage; chronic syndrome: fibrous liver, bile ducts grossly distended and thickened.
Diagnostic confirmation Acute syndrome: immature flukes in liver parenchyma at necropsy; chronic syndrome: characteristic eggs in feces, immunoassay of blood or milk.

ETIOLOGY

Fasciola hepatica is the most common and important liver fluke and has a cosmopolitan distribution in cooler climates. Lymnaeid mud snails are intermediate hosts and release the infective form, the metacercaria, onto herbage. Hepatic fascioliasis is mainly of economic importance in sheep or cattle but other species may provide a reservoir of infection. F. hepatica may infest all domestic animals, including Equidae and many wildlife species, but chronically infected sheep are the most important source of pasture contamination.2 Human cases are usually associated with the ingestion of marsh plants such as watercress. A similar but larger fluke, F. gigantica, is restricted to warmer regions including parts of Africa and Asia.

LIFECYCLE

Adult Fasciola live in bile ducts producing eggs that are excreted with the feces. Hatching occurs in moist conditions only after the first larval stage, the miracidium, has formed and when ambient temperatures rise above 5–6°C (41–43°F). Miracidia must find and invade the tissues of a suitable host snail within 24–30 h. After several cycles of asexual multiplication, the flukes leave the snail as cercariae. These attach to herbage and transform into metacercariae by secreting a tough protective cyst wall. After ingestion by the final host, each metacercaria releases an immature fluke which crosses the intestinal wall and migrates across the peritoneal cavity to the liver. The migration is sometimes misdirected and ectopic flukes can be found in the lungs, particularly in cattle. The young F. hepatica migrate through the hepatic parenchyma for about 4–5 weeks, growing from 0.1 to 10 mm. After entering the bile ducts, they more than double in size before egg laying starts about 10–12 weeks after infestation. Adult sheep and cattle may remain carriers for many years because of the longevity of the adult flukes.

EPIDEMIOLOGY

The risk of hepatic fascioliasis is determined by the numbers of infected lymnaeid snails in the grazing area. The disease has a predictable seasonal pattern in regions where snails are active for only
part of the year. Some lymnaeid snails have a more aquatic habit than others but all are restricted to damp or wet environments. In general, they prefer non-acidic low-lying swampy areas with slowly moving water, but land with small streams, springs, blocked drainage or spillages from, for example, water troughs may also be potentially hazardous for grazing stock. Land frequently irrigated is also highly suitable for infection to take place. Snails burrow into the soil to survive dry periods and release cercariae when free water is present. Snail habitats may be permanent or temporary. The latter expand and contract depending on water availability. Construction works, such as road building may alter drainage patterns and disease risk. Improvement of peaty pastures by lime application may increase risk by reducing soil acidity and allowing snail colonization.

Important host snails for *F. hepatica* include *Lymnaea truncatula* in the United Kingdom and Europe and *Galba bulimoides*, *G. B. techella* and others in the United States. *L. columella* has been identified as an intermediate host in Canada and more recently in Brazil. In New Zealand, *L. tomentosa* and *L. truncatula* have occurred without fasciolosis becoming a major problem but the introduction of *L. columella* markedly increased the range and severity of the disease.2 *L. tomentosa* is the major host snail in Australia, although *L. columella* has been reported to be present in non-farming areas and *L. viridis* has also been found.

**The main factors** determining the timing and severity of hepatic fasciolosis are those that influence the number of metacercariae accumulating on herbage. In particular, temperature and rainfall affect both the spatial and temporal abundance of snail hosts and the rate of development of fluke eggs and larvae.3 Temperatures above 10°C (50°F) are necessary before the snail hosts will breed or before *F. hepatica* can develop within the snail. No development therefore takes place during the winter in most countries.

The 'summer infection of the snail' by miracidia hatching from eggs in spring and early summer results in the emergence of cercariae and the consequent contamination of herbage some 5–8 weeks later.4 For any climatic region, cercarial shedding is a fairly regular occurrence with minor differences in timing determined by year-to-year variations in weather patterns.

The 'winter infection of the snail' is a separate cycle occurring when snails are exposed to miracidia in the autumn. Fluke development ceases in the snail during winter but resumes as temperatures rise the following spring. The relative import-

---

**Hepatic diseases associated with trematodes**

**Chronic hepatic fasciolosis** develops only after the adult flukes establish in the bile ducts. Here they cause cholangitis, biliary obstruction, fibrosis, and a leakage of plasma protein across the epithelium. Although this protein can be re-absorbed in the intestine, there is poor utilization and retention of nitrogen leading to hypoalbuminemia. There is also a loss of whole blood due to the feeding activities of the flukes. This exacerbates the hypoalbuminemia and eventually gives rise to anemia. It places a continuous drain on iron reserves so that the anemia, which is initially normochromic, becomes hypochromic. These changes are more severe in sheep on a low plane of nutrition.15 Chronic infection may limit growth rate and feed conversion in growing heifers and growth rate in beef cattle. *F. hepatica* infection has been reported to increase the susceptibility of cattle to *Salmonella dublin* and predispose to prolonged infection and fecal excretion.16 Infected ewes may have reduced fertility, growth rate, and wool production.21 Food intake is reduced and this leads to a reduction in efficiency of utilization of metabolizable energy and a reduction in calcium and protein deposition in the carcass.19

**The fibrotic response** of the liver to fluke-induced damage varies with the host and may partially account for differing species susceptibilities.3 The severe reaction in cattle, which includes calcification of the bile ducts, appears to hinder the establishment and feeding of challenge infections thereby reinforcing immune responses.7 Both horses and pigs are generally highly resistant to infection with *F. hepatica* but differ in their mode of resistance. Horses overcome the migrating fluke at an early stage so that few reach the liver, while in the pig the resistance mechanism operates in the liver parenchyma.20

**CLINICAL FINDINGS**

**Acute fasciolosis** Acute fasciolosis in sheep most often occurs as sudden death without other apparent clinical abnormality. It is usually seen in the summer and autumn but may occur at any time when sheep have the opportunity to graze heavily contaminated herbage. If the disease is observed clinically in sheep it is manifested by:

- Dullness
- Weakness
- Lack of appetite
- Pallor and edema of mucous and conjunctiva
- Pain when pressure is exerted over the area of the liver. Death occurs quickly and may be accompanied by...
Acute and chronic fasciolosis are opposite ends of the clinical spectrum. Intermediate forms occur and a subacute syndrome has been described in sheep. The major clinical signs are weight loss and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver.

**Subacute fasciolosis**

Acute and chronic fasciolosis are opposite ends of the clinical spectrum. Intermediate forms occur and a subacute syndrome has been described in sheep. The major clinical signs are weight loss and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver.

**Chronic fasciolosis**

Chronic fasciolosis does not become apparent until several weeks after the danger of acute disease has receded. Affected sheep lose weight, develop submandibular edema (bottle jaw), and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver. The course of the disease is often as long as 2–3 months in those which die; many survive but may remain in poor condition for longer periods. Cattle also lose weight, especially if lactating, milk production falls and anemia may develop.

**CLINICAL PATHOLOGY**

In acute fasciolosis there is a severe normochromic anemia, eosinophilia, and a severe hypoalbuminemia. Blood concentrations of a number of serum enzymes indicating liver damage are elevated. Glutamate dehydrogenase is of particular value when the young flukes are migrating through the liver parenchyma but concentrations fall after they enter the bile ducts. Increases in aspartate aminotransferase can be measured from 4 weeks and are useful as a measure of immature infection. Eggs will not be present in the feces as the flukes are still immature. Outbreaks are usually of relatively short duration; most deaths occur within a period of 2–3 weeks. Acute fasciolosis rarely occurs in cattle.

In subacute and chronic disease weight loss is associated with a severe hypochromic, macrocytic anemia, hypoalbuminemia and hyperglobulinemia. Submandibular edema and ascites occur only occasionally in the subacute condition but more frequently in the chronic disease. Serum gamma-glutamyl transpeptidase concentrations are raised by the activities of adult *F. hepatica* in the bile ducts. Other liver function tests are not significantly affected. A diagnosis of chronic hepatic fasciolosis can be confirmed by the detection of large numbers of characteristic, operculated fluke eggs in the feces. These eggs are thin-walled and stained yellow-brown by biliary pigments. They are dense and do not rise satisfactorily in all flotation solutions. Zinc sulfate solution (specific gravity 1.36) is recommended. Sedimentation tests are more accurate. Operculated fluke eggs are also characteristic of paramphistome infections and care is needed to differentiate the two.

**NECROPSY FINDINGS**

**Acute hepatic fasciolosis**

Acute hepatic fasciolosis is characterized by a badly damaged, swollen liver. The peritoneal cavity may contain an excess of blood-stained serum. The liver capsule has many small perforations and subcapsular hemorrhages. The parenchyma shows tracts of damaged tissue and is more friable than normal. The immature flukes are often so small that they are not readily discernible. They are most easily demonstrated by slicing a piece of liver thinly and shaking in water, permitting the flukes to settle to the bottom. The size of the flukes may allow estimation of the duration of the infection and this may help to determine which pastures are hazardous.

**Chronic hepatic fasciolosis**

Leaf-like flukes, measuring some 3.5 x 1 cm, are present in grossly enlarged and thickened bile ducts, particularly in the ventral lobe of the liver. The bile ducts may protrude above the surface of the liver and cysts may be present due to blockage of ducts with flukes and desquamated epithelial cells. Calcification of the bile duct walls is a common finding in cattle but not in sheep. The hepatic parenchyma is extensively fibrosed and the hepatic lymph nodes are dark brown in color. Anemia, edema, and emaciation are attendant abnormalities.

**DIAGNOSTIC CONFIRMATION**

In fluke endemic areas, fasciolosis must be considered as a possible factor in any outbreak of chronic ill health in sheep, either as the main cause or as a contributory factor along with other debilitating disease processes. To support a diagnosis, account should be taken of grazing history and the seasonality of fasciolosis in that locality. There should be fluke eggs in the feces and characteristic hepatic lesions at necropsy. As these may be ubiquitous findings in endemic areas, a judgment is necessary to determine whether the severity of the lesions is sufficient to incriminate the fluke as the sole or major contributing etiological factor. Enzyme-linked immunosassays (ELISA) are available for use with blood or milk and are particularly useful for the diagnosis of infection in cattle on an individual or herd basis. A rise in antibody can be detected by 2 weeks after infection and keeps rising until week 6. Coproantigen tests are being developed.

Acute disease can only be confirmed at necropsy.

**Chronic fasciolosis**

- Nutritional deficiencies of copper or cobalt
- Other internal parasitisms, including parasitic gastroenteritis (particularly *heponchosis*) in sheep and ostertagiosis in cattle
- Johne's disease

**TREATMENT**

Not all compounds are equally effective against all stages of development of *F. hepatica* in the body. At the time of writing triclabendazole comes closest to this ideal. For treatment of acute fasciolosis, it is essential to choose a product highly effective against the juveniles that damage the liver parenchyma. For chronic disease, a compound active against the adult fluke is required. Product safety is an important consideration as hepatic detoxicating mechanisms are already impaired. Flukicides can be used therapeutically for treating disease or prophylactically to prevent outbreaks. Some bind to plasma proteins (e.g. closantel) or erythrocytes (clorsulon), thereby extending their period of protection. All flukicides either have milk-withholding periods or are prohibited from use in animals providing milk for human consumption and so the best time to treat dairy cattle is at the drying off stage. Many products combine a flukicide with a nematocide, but these should only be used when there is simultaneous risk from the two types of parasite.

Triclabendazole is a compound specifically for use against *F. hepatica* in sheep (10 mg/kg) and cattle (12 mg/kg). Higher doses are required for the control of *F. gigantica* in buffalo. It is highly effective against all stages of fluke from 2 days old in sheep and 2 weeks in cattle and is the drug of choice in outbreaks of acute fluke disease. An 8 to 10-week dosing interval is recommended for use in control programs. Fluke populations resistant to triclabendazole have developed following intensive control regimens. Triclabendazole has been used with success in horses and donkeys (12 mg/kg) but is not licensed for this purpose.

Albendazole is a broad-spectrum compound also active against nematodes and...
cestodes. It is effective against adult *F. hepatica* at a dose-rate of 7.5 mg/kg in sheep and 10 mg/kg in cattle. It is ovicidal and will kill any *F. hepatica* eggs present in bile ducts or the alimentary tract at the time of treatment. Netobimin (20 mg/kg) is metabolized to albendazole in the body and has similar activity against *F. hepatica*.

Closantel will kill the majority of flukes older than 4 weeks in sheep at a dose rate of 10 mg/kg and will delay fluke egg output by animals grazing contaminated pasture for up to 12 weeks. It also has a residual effect against *H. contortus*.

Closuronal is combined in preparation with ivermectin for combined fluke and roundworm control in cattle. At the recommended dose rate of 2 mg/kg by SC injection, closuronal is effective against adult and 12 to 14-week immature flukes but activity against 8-week-old *F. hepatica* is variable.

Nitroxynil is given subcutaneously at 10 mg/kg and has good efficiency against the adult fluke but the dose has to be increased by up to 50% to obtain adequate control of acute disease. In sheep, spillage stains the fleece yellow. It cannot be given orally as the rumen microflora reduce the compound to an inactive metabolite.

Oxydolizane used in cattle (10 mg/kg) has a shorter milk withholding period than most other flucicloce. It has a significant effect against adult fluke but is inactive against immature forms. It may cause transient softening of feces. This compound has been combined with levamisole to provide activity against fluke and gastrointestinal nematodes.

**CONTROL**

Preventive measures are required in endemic areas as fasciolosis can cause death without warning or significant production losses. An integrated strategic approach is more cost beneficial than reliance on routine dosing and is less likely to induce anthelmintic resistance, but requires detailed knowledge of the local epidemiological cycle. In some countries where risk varies from year to year, predictions of likely disease levels are issued based on analysis of meteorological data and field observations. This enables control measures to be intensified when necessary. Computer models have been devised to assist this process.

Segregation of stock from sources of infection is the ideal method of control but not always feasible in practice. Identification and mapping of snail habitats may enable grazing plans to be devised that avoid danger areas at times of high risk. Where habitats are restricted in size and clearly defined, it may be possible to exclude stock by fencing.

Stock on heavily contaminated land may be protected from acute fasciolosis by taking advantage of the interval between the ingestion of metacercariae and the onset of disease. Treatment during this period with a product effective against young flukes will eliminate the migrating parasites before they cause serious liver damage. A further dose may be necessary depending on the duration of metacercarial intake and residual activity of the chosen product. Some metacercariae will continue to be ingested after the main danger period has passed and so treatment with a product active against adult *F. hepatica* will be needed some weeks later to insure against possible losses from chronic fasciolosis. Additional strategic doses may be required in regions where the winter infection of the snail is of significance. The precise timing of each of these doses depends on the local epidemiological pattern.

Reduction of pasture contamination with metacercariae will reduce future risk. This can be done by preventing the snails from becoming infected with *F. hepatica* or by diminishing the size of the snail population. To achieve the first objective, adult flukes should be eliminated from the bile ducts of all grazing stock in spring and early summer. This prevents egg excretion and minimizes the numbers of snail-seeking miracidia at this crucial stage in the epidemiological cycle. There may however be wildlife sources of *F. hepatica* eggs which cannot be controlled in this way. Snail numbers can be reduced by restricting the size of their habitat. This can be done, where feasible, by draining boggy areas and by making sure that ditches, land drains, water troughs etc. are well maintained.

With stall-fed buffaloes in the tropics advantage can be taken of the fact that the metacercariae of *F. gigantica* concentrate on the lower part of forage plants, for example rice straw. This can be cut off and used for other purposes while the upper, uninfected, part is fed to the farm stock.

Chemical snail control was widely practised before reliable animal treatments became available. Lymnaeid snails have enormous reproductive capacity and can quickly recolonize wet land. Application therefore has to be very thorough to have a significant season-long effect and there must be no possibility of invasion from neighboring land. Chemicals can be applied in spring for maximum impact on the snail population before breeding starts, or later in the season when snails are plentiful but before cercariae start to emerge. Efficacy is reduced if luxuriant plant growth hinders penetration to soil level. Inorganic compounds such as copper sulfate or sodium pentachlorophenate are effective but may be potentially hazardous to humans, stock, and the environment. Safer and more selective low-volume molluscicides such as *n*-trityl morpholine have been developed but are not commercially available at the time of writing.

**REFERENCES**

FASCIOLIDES

Fascioloides magna is a large liver fluke found mainly in North America but it also occurs in some European countries. It is a parasite of moose and deer but it can also infect other animals grazing the same pastures. Sheep and goats are particularly susceptible to infection. The prevalence of infestation in cattle may be high in endemic areas but they are seldom affected clinically.

The lifecycle in normal hosts is similar to that of Fasciola hepatica except that it grows up to 10 cm long and 3 cm broad in thin-walled cysts in the liver parenchyma. Connections between the cysts and the bile ducts allow the passage of eggs with the feces. Lymnaeid snails act as intermediate hosts and the final host is infected by ingesting metacercariae encysted on herbage. The fluke enters the liver after spending 3–4 weeks in the peritoneal cavity.

In sheep and goats the fluke continually migrates, never becoming encapsulated but forming large, thick tracts. Hepatic damage and hemorrhage are so severe that one or two flukes can be fatal. In cattle, necrotic tracts are seen in the parenchyma as well as dark, thick-walled cysts 4 cm in diameter. These have no connection to the bile ducts. Clinical signs in sheep and goats are similar to acute hepatic fasciolosis and infected animals can die without warning. Infestations in cattle are usually inapparent but may cause signs similar to chronic hepatic fasciolosis. Eggs may be found in the feces. These resemble F. hepatica eggs but are larger and have a small appendage at the blunter end.

Most anthelmintics effective against F. hepatica are also active against F. magna but few confirmatory reports have been published. Albendazole 10 mg/kg removed 74% of F. magna in naturally infected cattle, clofentril 15 mg/kg had good efficacy in sheep 8 weeks after infection, clofenvin gave variable results in cattle at 21 mg/kg, while triclabendazole 20 mg/kg was 99% effective in sheep when given 12 weeks postinfection.

REFERENCES

DICROCOELIUM

Dicrocoelium dendriticum is a small trematode widespread in Europe and Asia but with restricted distribution in North America and the British Isles. Its lifecycle differs from that of Fasciola hepatica in several ways. Eggs passed in the feces are eaten by land snails such as Helicella spp. and Cochlicopa lubrica. Cercariae are passed in slime balls used as food by ants of the genus Formica. Grazing animals become infected when they swallow ants containing metacercariae. The flukes travel up the common bile duct to settle in bile ducts within the liver. In contrast to F. hepatica, the intermediate hosts of D. dendriticum are not associated with wet habitats. Transmission can therefore occur on well drained farmland and even dry heathland pastures. Protective immunity is poor and heavy infections (tens of thousands) can accumulate.

Pathogenicity is low as D. dendriticum does not migrate across the liver parenchyma. Very heavy infections may cause ill-thrift. Lesions comprise fibrosis of the parenchyma and a proliferation and thickening of smaller bile ducts. Infectious necrotic hepatitis may develop as a result of infestation. At necropsy, D. dendriticum infection can be recognized as the flukes are smaller (0.5–1.5 cm) than F. hepatica, are lanceolate in shape and confined to the bile ducts. Eggs in feces are small, operculate, asymmetrical and dark brown in color. They are dense structures and flotation fluids with a high specific gravity, such as potassium iodomercureate solution (SG 1.44), are recommended. Treatment with albendazole at 15 mg/kg is effective as is netobimin at 20 mg/kg.

Stomach fluke disease (Intestinal amphistomosis)

Synopsis

Etiology Parapharyngotrematidae and related flukes. Epidemiology Infection by ingestion of metacercariae on herbage; geographical distribution, seasonality, and disease risk determined by occurrence of intermediate hosts (aquatic planorbid snails). Signs Severe enteritis, feline diarrhea. Clinical pathology Hypoalbuminemia; immature flukes may be passed in feces. Lesions Duodenal mucosa thickened, mucus blood stained with large numbers of small, flesh-colored flukes. Diagnostic confirmation Demonstration of immature flukes in feces. Treatment Oxydazionate.

Control Avoidance or drainage of snail habitats; anthelmintic treatments to prevent contamination of pastures with eggs.

ETIOLOGY

Intestinal amphistomosis is associated with paramphistome flukes in the duodenum migrating towards the fore­ stomachs. Cattle and, to a lesser extent, sheep are at risk of infection. The param­ phistomes are cosmopolitan but disease is most common in warmer regions, particularly Australasia, Africa, and India. Commonly recorded paramphistome species include Parapharyngotrema cervi, P. microbothrioides, P. loricis, P. ichikawai, P. microbothrium, Calicophoron calicophorum, Ceylonocotyle streptocotyle, Calicophoron ijimai, and Cotylophoron cotylophorum.

LIFECYCLE

The lifecycle is similar to that of Fasciola hepatica except that the intermediate hosts are planorbid snails and the immature flukes migrate proximally along the duodenum and through the abo­ masum to reach their predilection site in the rumen and reticulum. The period required for maturation varies from 6 weeks to 4 months.

EPIDEMIOLOGY

Planorbid snails are aquatic. They are more adaptable and occupy more diverse habitats than lymnaeid snails. Thus zones of endemicity for intestinal amphistomosis and hepatic fasciolosis do not necessarily coincide. Most outbreaks of disease occur during the late summer, autumn, and early winter when pastures are heavily contaminated with encysted cercariae. Planorbid snails multiply very rapidly in warm, watery environments but can subsequently survive dry conditions. Metacercariae are therefore found on
pastures prone to flooding as well as on herbage in and around ponds, streams and other water sources. All ages of cattle, sheep, goats, and wild ruminants grazing near water or on land liable to flooding may be affected but young cattle in the yearling class are the usual subjects. It is possible that some degree of immunity develops.

PATHOGENESIS
The immature flukes excyst in the duodenum or mid-to-proximal jejunum. As they migrate they attach firmly to the mucosa and may penetrate as far as the muscularis mucosa. Damage is related to the numbers of migrating flukes and increases in intensity from localized enteritis through patches of villous atrophy to severe destruction of the mucosa. Clinical and production effects are dependent upon the extent of the lesions as some compensation for functional deficiency can take place in the undamaged lower small intestine. The presence of mature flukes in the rumen does not usually elicit any significant response but in massive infections papillae are short and red, becoming fused into aggregations with ruminal contents adhering firmly to the surface.

CLINICAL FINDINGS
Severe enteritis associated with enormous numbers of migrating flukes in the duodenum seems to be the only manifestation of disease. A characteristic and persistent fetal diarrhea is accompanied by weakness, depression, dehydration and anorexia. There may also be submaxillary edema and obvious pallor of the mucosa. Death usually occurs 15–20 days after the first signs appear. The mortality rate in heavily infected animals may be high. Mature flukes in the forestomachs of animals normally cause little harm, although loss of weight, anemia, a rough dry coat, and a drop in production, have been ascribed to heavy infestations.

CLINICAL PATHOLOGY
A sedimentation and decanting technique may be used to find immature flukes passed in feces. The larvae are round with prominent anterior and posterior suckers. Because the disease is caused by immature forms, eggs are not usually present in the feces, although they may be detectable in older animals in the same herd. Paramphistome eggs are dense structures and so sedimentation methods for detection are preferred to flotation. The eggs have a distinct operculum and resemble those of *F. hepatica*, but the shell is colorless. Blood biochemistry reveals a marked drop in total plasma protein, due largely to a fall in plasma albumin.

NECROPSY FINDINGS
There is muscular atrophy, subcutaneous edema and accumulations of fluid in the body cavities, and the fat deposits are gelatinous. In the upper part of the duodenum the mucosa is thickened, covered with blood-stained mucus and there are patches of hemorrhage under the serosa. Large numbers of small, flesh-colored flukes (3–4 mm long and 1–2 mm wide) are present in this area but decrease in number towards the ileum. There may be none in the abomasum and forestomachs. There may be a few in the peritoneal cavity and on histological examination the young flukes are present not only on the mucosal surface but are also embedded in the mucosa and deeper layers.

DIAGNOSTIC CONFIRMATION
The occurrence in yearling cattle of a severe enteritis, unaccompanied by fever, in environmental conditions suitable for the propagation of flukes and where host snails can be found should arouse suspicion of intestinal amoebiasis. Confirmation depends on demonstration of immature flukes in feces or at necropsy. Care is needed as the small parasites are easily missed.

Differential Diagnosis
- Nutritional deficiency of copper
- Infestation intestinal roundworms
- Infectious enteritides, but these are usually accompanied by fever
- Johne’s disease in adult animals, but this is a much more chronic disease
- Poisonings, including many weeds, inorganic arsenic and lead.

TREATMENT
Few drugs are highly effective. Two doses of oxyclozanide 18.7 mg/kg 2 days apart, or a single dose of hexachlorophene 20 mg/kg, give consistent results against immature paramphistomes in cattle, but hexachlorophene may show toxicity at this dose rate. Niclosamide 160 mg/kg as a single dose or as two doses 3 days apart is effective but somewhat variable; however, it has good activity at 100 mg/kg against immature paramphistomes in sheep. Bithionol has been used in Asia and Africa.

CONTROL
Animals should, where possible, be denied access to contaminated areas. Otherwise, regular treatments will be needed. Snails quickly repopulate pastures once they become wet and stock should be removed before the intermediate hosts start to sheds large numbers of cercariae (1–2 months from infection of the snail depending on temperature). Metacercariae may persist on pasture for up to 2 or 3 months after flood water has dried out.

In areas where paramphistomes are a regular problem, knowledge of the local epidemiological cycle will help determine optimum times for prophylactic treatments. These are aimed at killing migrating immature flukes before they cause disease and at reducing egg-output by adult worms, thereby minimizing opportunity for snails to become infected. Drainage of low-lying areas and destruction of host snails by the use of molluscicides could be considered.

Tapeworm infestations
ADULT TAPEWORM INFESTATION

Synopsis
Etiology Cestodes belonging to the anoplocephalid family, including *Moniezia* spp. in ruminants and *Anoplocephala* spp. in horses.

Epidemiology Transmission by ingestion of infected free-living pasture (oribatid) mites.

Signs Little pathogenicity but heavy infestation may cause failure to thrive and, in horses, increased risk of ileocecal colic.

Clinical pathology Demonstration of tapeworm eggs in feces.

Lesions Horse: mild inflammation of intestinal mucosa with small ulcers.

Diagnostic confirmation Tapeworm segments around tail base or on feces; eggs in feces.

Control If necessary, periodic dosing is the only feasible option.

ETIOLOGY
The common anoplocephalid tapeworms of ruminants, *Moniezia expansa*, *M. benedeni*, and *Thysaniezia* (syn. *Helicotometra giardi* also known as *T. ovilla*) are cosmopolitan,
while *Avitellina* spp. occur mainly in Mediterranean countries and India, *Stilesia hepatica* in Africa and *Thysanosoma actinioide* in North America.

In horses, *Anoplocephala magna*, *A. perfoliata*, and *Anoplocephaloides* (syn. *Paranoplocephala mammillana*) are cosmopolitan in their distribution.

**LIFE CYCLE**

The lifecycles of all the anoplocephalid tapeworms are very similar. Eggs, which are immediately infective, pass in the feces of the host, either singly or protected within a tapeworm segment. These are ingested by free-living pasture (oribatid) mites and the intermediate stage (the metacestode) forms. Mature tapeworms develop when the primary host accidentally swallows infected mites while grazing. Most species establish in the small intestine, but *T. actinioide* also invades biliary and pancreatic ducts, while *A. perfoliata* is found around the ileocecal junction and *S. hepatica* lives in the bile ducts. Lengths vary with species: *A. perfoliata* grows to 4–8 cm while *Moniezia* may be over 2 m.

**EPIDEMIOLOGY**

Oribatid mites are ubiquitous but most numerous on permanent pastures in the summer months. All grazing animals are therefore potentially at risk.

**PATHOGENESIS**

In ruminants, anoplocephalid tapeworms have little apparent effect on health. In heavy infestations, it has been postulated that they may compete for nutrients, excrete toxic materials or, because of their length, interfere with the motility of the gut. Very heavy burdens of *M. expansa* in lambs have been associated with outbreaks of enterotoxaemia. Pancreatic and biliary duct species cause little harm but heavy infestations are asymptomatic but, occasionally, heavy infestations may be associated with a range of abdominal conditions including colic, perforation of the cecum, ileocecal, coccidial, and ileoileal intussusception, colonic, and cecal torsion, ileal thickening and obstruction.

**CLINICAL PATHOLOGY**

Shed tapeworm segments may be visible macroscopically on the skin and hair around the tail base or in the feces. Eggs may be present in feces.

**NECROPSY FINDINGS**

The site of attachment on the intestinal mucosa may be indicated by the presence of a small ulcer and a mild inflammatory response. In the case of infestations with *T. actinioide* and *S. hepatica*, the presence of worms in the biliary and pancreatic ducts is accompanied by fibrosis and thickening of duct walls.

**DIAGNOSTIC CONFIRMATION**

Shed segments are much wider than they are long. They can be seen to be full of characteristic eggs if broken in a drop of water on a slide and examined microscopically. Anoplocephalid eggs are roughly D-shaped, thick-shelled, and contain an embryo within a chitinous ring. They are not easy to find in feces. Centrifugation or flotation using a saturated sugar solution is recommended for diagnosis in horses. At best the sensitivity of such techniques is only 60% for light infections rising to 90% for heavy burdens, and so repeat samples may be needed to demonstrate the presence of the parasite. Methods have been devised for detection of specific antibodies in serum or antigen in feces but are not as yet generally available.

**DIFFERENTIAL DIAGNOSIS**

- Other causes of unthriftness
- In horses, other causes of colic.

**TREATMENT**

For ruminants, praziquantel 3.75 mg/kg is highly effective against *Moniezia* but higher doses are required for *Thysanosoma* spp. (5 mg/kg), *Avitellina* (7.5 mg/kg) and *Stilesia hepatica* (15 mg/kg). Some benzimidazoles and pro-benzimidazoles drugs have cestocidal activity in ruminants, including albendazole, fenbendazole, mebendazole, nitobemid and oxendazole. The efficacy of some of these compounds against *Moniezia* may be variable. Albendazole at 7.5 mg/kg is effective against cestodes in the bile ducts.

For horses, pyrantel embonate at 38 mg/kg (i.e. double the standard dose for roundworm control) is an established treatment for *A. perfoliata* but is ineffective against *A. mammillana*. More recently praziquantel has been shown to provide high efficacy against *A. perfoliata* at doses of 1–2.5 mg/kg and *A. mammillana*. Such treatment may half the estimated risk of tapeworm associated colic.

**CONTROL**

Control of the mites which act as intermediate hosts is impractical. If a potential problem is perceived in, for example, valuable horses, consideration could be given to reducing the numbers of oribatid mites by ploughing permanent pasture and reseeding. Otherwise stable or tactical dosing in early summer and autumn are the only options.

**REFERENCES**

**LARVAL TAPEWORM INFESTATION**

Livestock may act as the intermediate hosts for the tapeworms of humans and other animals. The larval tapeworms...
(metacestodes) develop as fluid-filled cysts, each at a typical site in the body. They act as space-occupying lesions and cause condemnation at meat inspection. Cattle around the world may harbor the metacestode of *Taenia saginata* (the beef tapeworm of humans), also known as *Cysticercus bovis*, in their striated musculature. *T. solium* (the pork tapeworm of humans) occurs similarly in pigs (known as *C. cellulosae*), mainly in poorer regions. The recently discovered *T. asiatica*, found only in East Asia, is closely related to *T. saginata* but uses pigs as its intermediate host. Cysts in the musculature of sheep (known as *C. ovis*) are the intermediate form of a dog cestode (*T. ovis*). Hydatid cysts (*Echinococcus granulosus*), which develop in the lungs and/or liver of sheep, cattle and horses are also acquired from tapeworm eggs excreted by infected dogs and wild canids. These metacestodes rarely cause clinical disease in veterinary species (although some are serious zoonoses) and so the reader is referred to parasitology textbooks for detailed information.

Clinical disease is, however, associated with two other metacestodes. That of *Taenia (Multiceps) multiceps* causes coenurosis (' gid') in sheep, which is described under diseases of the nervous system. *Taenia hydatigena* metacestodes are normally asymptomatic but if a sheep or goat swallows a whole tapeworm segment, which may contain 100 000 eggs, sudden death may occur as massive numbers of developing metacestodes (known as cisticerci) migrate through the liver parenchyma. This condition (hepatitis cisticercosis) resembles acute hepatic fasciolosis but is an individual rather than a flock problem.

Diseases associated with arthropod parasites

Gasterophilus spp. infestation (stomach bot) 1585
Oestrus ovis infestation (nasal bots) 1586
Hypoderma spp. infestation (warble flies) 1587

Infestations with larvae of Gasterophilus spp. have a widespread distribution. They cause a chronic gastritis and a loss of condition in infested horses, donkeys, and mules. Reduced performance is often attributed to this infestation. On rare occasions they cause perforation of the stomach and death.

GASTEROPHILUS SPP. INFESTATION (STOMACH BOT)

Infestations with larvae of Gasterophilus spp. have a widespread distribution. They cause a chronic gastritis and a loss of condition in infested horses, donkeys, and mules. Reduced performance is often attributed to this infestation. On rare occasions they cause perforation of the stomach and death.

| Treatment | Ivermectin, trichlormethoximecetin. |
| Control | Treatment given when fly activity has ceased and when larvae are in stomach - usually two treatments in mid and late winter. Fringes and tassels protect against worry associated with one species of fly. |

ETIOLOGY

Five species of flies of are known to parasitize domestic equids; Gasterophilus nasalis, G. intestinalis, G. haemorrhoidalis, G. pecorum, and G. inermis. Their larvae are the ‘stomach bots’ of horses, donkeys, and mules. Three species, G. intestinalis, G. nasalis, and G. haemorrhoidalis, are the most important and have a world wide distribution. The later larval stages inhabit the stomach and duodenum. These creamy pink larvae are thick, segmented, and about 5–15 mm long. The adult flies are golden brown, hairy, and about the size of a bee with two wings and vestigial mouth parts.

LIFE CYCLE AND EPIDEMIOLOGY

Flies do not feed and only live a few days. They are active during the summer months and there may be overlap among the species in their periods of activity. In areas with mild winters the flies may be active throughout the year. In colder regions fly activity ceases with the first frost and there is usually only a single generation per year. In these regions the second and third instars remain in the stomach over the winter.

Eggs are attached to hairs while the fly hovers close to the horse. Feecidity is roughly correlated to the size of the fly. G. haemorrhoidalis matures about 50–200 eggs, G. nasalis 300–500 eggs, and G. intestinalis up to 1000. Eggs of the various species are laid in specific locations and are attached in a specific manner, allowing identification of eggs to species. The eggs are laid on the horse’s coat except for G. pecorum which lays up to 2000 eggs in batches of 100–200 on pasture plants. The eggs of G. pecorum and G. haemorrhoidalis are dark brown; the eggs of the others are yellow and are readily visible glued to the hairs, usually one to a hair. The eggs of G. intestinalis, the most common fly, are laid on the front legs, particularly the lower parts; those of G. nasalis in the intermandibular area; the others species’ eggs are laid on the cheeks and lips.

The eggs are ready to hatch in about 2–10 days and the first instars enter the mouth either by host biting or licking or by subcutaneous migration from the cheeks into the oral cavity. The eggs of G. intestinalis and G. pecorum require a stimulus, provided by licking (moisture) or rubbing (friction), before they will hatch. The larvae penetrate oral mucosa, migrate to inner surfaces and emerge in the inter-dental spaces. The larvae of G. intestinalis penetrate the anterior end of the tongue and burrow in the buccal mucosa for about 3–4 weeks before invading pockets between the teeth or between the gum and molars. G. nasalis may also accumulate in pockets alongside the molars and cause mouth irritation. G. haemorrhoidalis can penetrate the skin of the cheek and after wandering in the tissues of the mouth may attach in the pharynx. The second instar of G. intestinalis may also attach for a few days to the pharynx and the sides of the epiglottis before passing to the stomach. The first
instars of *G. pecorum* burrow into the mucous membranes of the hard palate, cheek and tongue where they develop into second instars. They then move to the pharynx where they develop into the third instar. Occasional larvae migrate to abnormal sites including the brain, the cranial sinuses, the heart, and lungs.

Third instars of *G. intestinalis* are found attached to the mucosa, usually in bunches, at the junction of the glandular and non-glandular portion of the stomach, where they become attached to the mucosa. *G. nasalis* larvae are found in the pyloric region of the stomach and the duodenum. *G. pecorum* larvae may be found in the pharynx and upper part of the esophagus and in the fundus of the stomach. *G. haemorrhoidalis* larvae are found in the tongue, the pharynx, and the gastric fundus.

In the host, two molts are made and the larvae pass out in the droppings 10–12 months after infestation, usually in the spring and early summer. Some larvae may attach temporarily to the rectal mucosa on their way through. The larvae migrate into the ground, pupate, and adult flies emerge after 3–5 weeks to recommence the late summer attacks on horses.

### PATHOGENESIS

The adult fly causes considerable annoyance when ovipositing. The droning noise and the sudden attacks to lay eggs causes head tossing and running in the host. *G. nasalis* is particularly troublesome as it darts at the lips and throat.

There is some doubt as to the importance of the lesions associated with the larvae. At the sites where they adhere there is an area of thickening and inflammation and in rare cases gastric perforation occurs. It is probable that there is some chronic gastritis and interference with digestion in most infestations. *G. intestinalis*, the most common species, attaches to the squamous epithelium and this has a relatively slight impact on digestion in the horse. However, the ulceration, edema, and abscession associated with this species cannot be overlooked and one must expect some effect from such lesions although it is difficult, in practice, to separate these findings from those associated with a concurrent worm burden. Occasional perforation of the gut has been documented. The larvae do not remove sufficient blood to cause anemia, feeding mostly on tissue exudate. In rare cases pleurisy may occur following perforation of the esophagus close to the cardia. In very heavy infestations with *G. pecorum* the presence of large numbers of larvae (100–500) on the soft palate and base of the tongue can cause stomatitis and some deaths. Migration of first instars in the tongue and interdental gingiva and the aggregation of larvae in periodontal pockets may produce irritation or pain and may prevent foals eating.

### CLINICAL FINDINGS

A non-specific syndrome of unthriftiness, poor coat, occasional mild colic, and lack of appetite, plus bad temper and unwillingness to work is usually ascribed to bot infestations. Adult flies frighten horses by their hovering, darting flight, especially around the head of the horse, and may be a cause of shying and balding.

### CLINICAL PATHOLOGY

The eggs on the hairs can be seen by direct inspection but the presence of larvae in the stomach and intestines can only be detected after treatment with a suitable boticide.

### NECROPSY FINDINGS

A few larvae are present in the stomach of most horses at necropsy but clinical illness is usually associated with very large numbers. The areas of larval attachment are pitted and the gastric wall thickened. There may be an adhesive peritonitis with attachment and abscession of the spleen over such areas.

### DIFFERENTIAL DIAGNOSIS

The syndrome produced is not sufficiently characteristic to make antemortem diagnosis possible and bot infestations are commonly associated with helminth infestations which produce most of the signs observed. A tentative diagnosis of infestation of the gums can be made by signs of pain on mastication and the presence of bot-fly eggs on the horse at that time. A variety of serologic tests, including an ELISA, have been evaluated and found to be generally specific and sensitive. There has been no further development of a practical test. Endoscopy using a video gastroscope has been applied to the diagnosis of gastrophilosis, although its use has been confined to use in drug efficacy studies.

### TREATMENT

Many of the organophosphates are effective. Trichlorfon 40 mg/kg is effective and is usually given with a benzimidazole to control strongyles as a common broad-spectrum mixture in the horse. It can also be used as a paste. Ivermectin 0.2 mg/kg has high efficacy against the oral and gastric *Gasterophilus* larvae as well as all gastrointestinal nematodes, including migrating and hypobiotic large strongyles, *Oechocerca cervicalis* and larval stages of *Habronema* spp. and *Draschia megastoma* in the skin. Ivermectin has gained high acceptance in horse practice. Moxidectin 2% oral gel has been shown to have excellent efficacy.

### CONTROL

Treatment should preferably be administered after fly activity has ceased and the larvae have reached the stomach but before gastric damage has occurred. In most districts two doses should be given in winter, or in late winter and early spring. In foals showing pain on mastication, treatment with ivermectin paste or dichlorvos should be given as needed throughout the fly season.

The use of repellents or agents to kill the larvae in manure has not been successful, nor has bathing the affected horses to encourage mass hatching and death of the larvae. The use of fringes, veils and tassels on the head harness helps protect horses against fly worry but is of little use in preventing bot infestation.

### REFERENCES

### OESTRUS OVIS INFESTATION (NASAL BOTS)

Infestation of sheep and goats with larvae of the nasal bot fly has a serious effect on the productivity and welfare of both sheep and goats. Adult activity induces stress responses and significant behavioral change. Larval infestation induces moderate to severe pathology that reduces productivity.

Similar flies are known to affect horses, donkeys, and mules (*Rhinoestrus spp.*) in the Mediterranean region and to affect camels (*Cephenemyia titillator*) in Africa as well as Australia. Wild ungulates are affected by nasal bots (e.g. *Cephenemyia spp.*). Very little is known about the pathology and impact of these later groups of flies, but similarities in life history suggest their affects will be similar to that discussed below.

### Synopsis

**Etiology** One species, *Oestrus ovis*, which inhabits the nasal passages and sinuses of sheep and goats.

**Epidemiology** Larvae are sprayed onto the nares of hosts by passing females. Flies are active during spring and summer, inducing behavioral changes in hosts under attack. In temperate climates there is only a single generation per year, but in warmer climates two generations are known. First instars in the nasal passages undergo hypobiosis during winter or hot summer when survival of pupae or adults is low.
The period of development can vary from weeks to several months after which they resume development when conditions are more favorable.

**Clinical signs** Shortly after arrival of the larvae an increase in nasal discharge and sneezing are evident. As the infestations develop the amount of discharge increases and the nostrils may become caked with dust and debris forcing the infected animals to breathe through their mouth.

**Clinical pathology** Changes are noted to the mucosa of the ethmoid and sinus regions. Inflammation of these surface tissues is evident and increases as the larva become mature. Changes to the epithelial structure are noted including the erosion of the surface ciliary covering and a breakdown in epithelial cell integrity. Abrasive action of the body armor as well as the activity of proteolytic enzymes excreted/secreted by the larvae are responsible for the pathology. Secondary effects include the induction of lung lesions and the activation of latent "orf" infections. Diagnostic confirmation. Behavioral changes during fly season and nasal discharge.

**Differential diagnosis** Unthriftiness usually associated with helminth infection.

**Treatment** Macrocyclic lactone endectocides, closurion.

**Control** Treatment given when fly activity has ceased.

**Etiology**
A single species, known as the sheep nose bot, affects sheep and goats in most regions, but is particularly significant in the Mediterranean basin, central America, southern Africa, and eastern Europe. The larvae inhabit the nasal passages and sinuses, eventually being expelled through the nares. Goats are less dramatically affected than sheep. The slightly dorsally flattened, segmented larvae are light cream in color, but as they reach maturity dark bands appear on each segment.

**Life Cycle and Epidemiology**
The adult fly is stout, mottled gray in color, and about 1 cm long. Its mouthparts are rudimentary and it does not feed. In North America, flies emerge in the late spring, and the females begin larviposition activities approximately 2–3 weeks later.

Adult flies attempting to deposit larvae on the nares annoy the sheep and cause them to bunch or seek shelter. Stamping of the feet and shaking of the head are common. Sheep may bunch together and press their heads into the fleece of others. Fly activity occurs primarily during the warmer parts of the day, but still may result in the loss of a good deal of grazing time. Behavioral changes in goats are less dramatic, presumably because of their browsing habit.

Larval development takes place within the dorsal turbinates and frontal sinuses. The period of development can vary from 3 weeks to several months after which they migrate to the nostrils. Larvae feed on the mucosal secretions and cells eroded from the mucosal epithelium. The larvae are thick, yellow-white in color and when mature there is a dark dorsal band on each segment. The vertical surface has rows of small spines on each segment. Mature larvae exit the host, usually during a bout of sneezing, and actively burrow beneath the upper layers of soil and ground litter. Pupation occurs at these locations and development of the adults requires 4–5 weeks, but may take longer at low temperatures. In temperate areas there may be one or two generations per year but several generations may be completed in hot areas. *O. avis* is adapted to the various climates prevailing wherever sheep and goats are kept. When winters are cold, the larvae can overwinter by remaining dormant in the first instar (hypobiosis), but in warmer climates development may continue throughout the winter. In those regions where summer temperatures are extreme the larvae will also undergo hypobiosis.

*O. avis* are an important zoonosis as the females may larviposit in the eye, nose or on the lips of humans. In some countries ophthalmomyiasis or infection of the upper respiratory tract is a common occurrence.

**Pathogenesis**
The stress of the larviposition attacks can be significant with reduced grazing time and over-heating resulting from bunching. Herdsman find the animals are more nervous and difficult during the fly activity periods.

Larvae induce a gradually increasing rhinitis and sinusitis as the infestation persists. Marked changes in the structure of the epithelial tissues are noted with a marked cellular degeneration and a loss of the ciliary layer. The changes are a result of both mechanical activity of the larval spines and mouthhooks as well as the effect of proteolytic enzymes excreted or secreted.

Varying degrees of mucous discharge are observed in the later stages of the infestation. This can lead to the nostrils being occluded by adherent straw and dust.

**Clinical Findings**
Early in the infestation there is a distinct rhinitis accompanied by a muco- to mucopurulent discharge. Later as larvae mature, a sinusitis is evident. Presence of mature larvae in nasal cavities may induce excessive sneezing which assists larval exit.

Activity of the larvae in the nasal cavities and the changes they induce lead to an increased incidence of secondary pathology. The number and severity of lung abscesses are more significant in nose bot infected sheep. The presence of bots also is correlated with increased carcinomas and may lead to reactivation of latent "orf" symptoms.

**Differential Diagnosis**
The behavioral changes during fly activity, including bunching and burying of noses in neighbors' fleece is a reliable indicator of fly attack. Nasal discharge and excessive sneezing are highly suggestive, but not definitive. Infested sheep and goats develop some level of immunity form exposure to larval antigens. An ELISA for detection of antibodies to larval secretions has been developed.

**Treatment**
Clostaril 7.5 mg/kg and ivermectin 0.2 mg/kg as well as other macrocyclic lactones are effective and the use of these compounds for fluke or worm control also controls nasal bots.

**Control**
Treatment should preferably be applied after the cessation of fly activity, although it may be necessary to apply treatments during prolonged fly activity in order to give relief.

**References**

**Hypoderma spp. Infestation (Warble Flies)**
Infestations of cattle with the larvae of *Hypoderma* spp. cause serious damage to hides and carcasses, as well as production losses. Occasional deaths from anaphylactic shock or toxemia and damage to the central nervous system or esophagus. Several other flies with very similar life histories similarly affect goats (*Przewalskiana silenus*), and semi-domestic reindeer (*Hypoderma tarandi*) in addition to affecting the well-being of wild ruminants.

**Synopsis**

**Epidemiology** Eggs attached to hair in spring to late summer, larvae penetrate skin and migrate to esophagus (*H. lineatum*) or spine (*H. bovis*) where they stay for 6–7 months; they then move to subdermal tissue along the back and after
2–3 months emerge from the breathing hole, fall to the ground, pupate and emerge as adult flies 3–5 weeks later.

**Clinical signs** Poor growth and production. Larvae in the back causes obvious swellings while larvae in the spinal cage may cause posterior paralysis. Treatment of larvae while they are in the esophagus may cause massive edema, and edema and paraplegia may occur if animals are treated when larvae are in the spinal canal.

**Clinical pathology** An ELISA is available.

**Lesions** Larvae are found in discolored tissue.

**Diagnostic confirmation** Swellings along back characteristic. Paraplegia occurs about 72 hours after treatment.

**Differential diagnosis** Traumatic injury to the spine; aberrant S. vulgaris larvae in the horse.

**Treatment** Organophosphates, macrocyclic lactone endectocides.

**Control** Treatments are given so as to avoid treating when larvae are in the esophagus or spinal canal. (Usually treated in autumn and spring but varies with location.)

---

**ETIOLOGY**

There are two species which specifically parasitize cattle: *Hypoderma bovis* and *H. lineatum*. A third species, *H. sinense*, affects cattle and yaks in central Asia. The adult flies are robust and hairy, about the size of a bee (12–18 mm long), are yellow-orange in color and have two wings. They are not easily seen because of the rapidity of their flight. Repeated infestation results in an acquired immunity that results in older animals being less severely affected than younger animals.

Horses are occasionally infected with *Hypoderma* species of cattle. The larvae are found in subcutaneous cysts on the back, but have not been reported to complete development. This location causes problems if they are in the saddle region.

Losses to the cattle industry associated with warble fly have not been estimated recently, but in 1965 the loss was estimated to be $US192 million per annum in the United States, and in 1976 approximately CANS$100 million in Canada. In 1982 the cost of warble fly was estimated as £35 million for Great Britain, but the parasite has now been eradicated from the UK and Ireland. Advent of the macrocyclic lactone endectocides have greatly reduced the prevalence of the cattle species in North America, but they persist in localized areas.

*Hypoderma tarandi*, *H. acteon*, and *H. diana* infect reindeer/caribou and deer respectively. *H. diana* is found throughout Europe in several deer species but may also occur in sheep. *H. actaeon*, also found throughout Europe, is known only from the red deer. These species do not undergo deep tissue migrations that characterize the lifecycle of the cattle species.

*Przewalskiana silenus* is similar to the above and parasitizes goats in the Mediterranean basin, parts of eastern Europe as well as in Pakistan and India. This species also does not have a deep tissue migration and larvae tend to develop subcutaneously very near the site of initial skin penetration. The losses resulting from this parasite are significant and result from reductions in carcass quality and reduced animal health.

The larvae of *Dermatobia hominis*, a small (12 mm long) related fly, parasitize a wide variety of hosts and cause major economic losses to cattle production in South America. They also affect man and are a major zoonosis for travelers in the region. Mature larvae are about 2.5 cm long and develop in a subcutaneous cyst that can be quite painful. Female *Dermatobia* oviposit on zoophilous, "porter" flies such as mosquitoes and stable flies which they catch "on the wing". The eggs are transported to mammalian hosts where they hatch in response to increased temperature as the fly lands. Larvae penetrate the skin, but do not migrate. Treatment and control measures are the same as for *H. bovis*.

**LIFE CYCLE AND EPIDEMIOLOGY**

Warble flies are common parasites of cattle in the northern hemisphere, including North America, Europe, and Asia. Precise distribution of these parasites has been changing recently with the widespread use of macrocyclic lactone endectocides and the adoption of eradication programs in many European countries. Infestations south of the equator are rare and are the result of imported cattle, although endemic cases have occurred in Chile.

Adult flies are active in the spring to late summer. *H. lineatum* usually appearing 3–4 weeks before *H. bovis*. *H. lineatum* attaches up 600 eggs, in strings of 5–25, to hairs on the legs or lower parts of the body while *H. bovis* attaches eggs, one at a time, to hairs on the rump and upper parts of the hindleg. The oviposition flight of *H. bovis*, darting in to lay each egg, will terrorize cattle. Eggs hatch in 4–6 days. The larvae penetrate the skin using protease enzymes and migrate through connective tissues to reach the esophagus (*H. lineatum*) or the epididymal fat in the spine (*H. bovis*) where they stay, feeding and growing, for 2–4 months. They subsequently continue their migration to reach the subdermal tissue of the back in the early spring. Here they make a breathing hole and become encased in a granulomatous cyst. They complete development in 1–2 months, passing through second and third instars and emerge through the hole, fall to the ground and pupate. Adult flies emerge some 3–5 weeks later. The fully developed larvae are thick and long (25–30 mm), light cream in color, but darkening to almost black as mature third instars. A single animal may have up to 300 larvae each developing with granulomatous cysts, with breathing holes, under the skin of the back.

The timing of the life cycle, i.e. the period when grubs are present in the animals and the time at which the flies are present in large numbers, varies with the climate and is of importance in control programs. *H. lineatum* generally is 1–2 months ahead of *H. bovis* and where the two flies are present both "grub" and "fly" seasons may be very long. In the southern United States the "fly season" is February and March; in Canada it is June to August. The period when grubs are present in the back is December in the south and February to May in Canada. In Europe the larvae begin to move to the back in January to July.

**PATHOGENESIS**

Migrating first instars cause little damage as they use their proteolytic enzymes to migrate through connective tissue. The enzymes, however, have an anti-inflammatory effect, partially through cleavage of complement components. Larvae maturing under the skin of the back form holes in the skin and the reaction of the host encloses each grub within a granulomatous cyst. On rare occasions an anaphylactic reaction may occur in a sensitized animal as the result of death of migrating larvae; chance migration into the brain may also occur. Intracranial myiasis due to *H. bovis* has also been recorded in the horse. Treatment of animals when the first instars are in the esophagus may cause a massive inflammatory edema which may prevent feeding and swallowing of saliva; eructation may stop and bloating may occur. Treatment of *H. bovis* while it is in the spinal canal may also cause edema and mild to severe paraplegia.

**CLINICAL FINDINGS**

If the fly population is heavy, cattle at pasture may be hindered by their attacks which disrupt grazing and breeding behavior. Avoidance behavior, called gadding, may result in injury as cattle run into fences and other natural obstructions. Heavy infestations with larvae are commonly associated with poor growth, condition and production but such heavy infestations are often complicated by other forms of mismanagement including malnutrition and parasitic gastroenteritis. Immunosuppression results from the effect of larval secretions. Infected cattle milk poorly and a considerable increase in milk production and milk fat occurs after treatment.
The presence of the subcutaneous larvae causes obvious swelling with pain on touch. The swellings are usually soft and fluctuating. There may be as many as 200–300 such lesions on the back of one animal. With involvement of the spinal cord there is a sudden onset of posterior paralysis without fever and without other systemic signs. The suddenness of onset and the failure of the disease to progress usually suggest traumatic injury. A similar disease can occur in horses and is reputed to be more common in horses than in cattle.

**CLINICAL PATHOLOGY**

An ELISA which detects antibodies to the secreted enzymes of *H. lineatum* and *H. bovis* has been developed. It has been used in the eradication program in Great Britain and in France. In addition, an antigen capture ELISA, used to detect the presence of circulating quantities of the predominant larval enzyme has been developed. This will be useful in differentiating active from cleared infestations and will be useful in detailed surveillance programs.

**NECROPSY FINDINGS**

The first instars, migrating within connective tissue, are usually surrounded by a zone of yellow-green discoloration. Later larval stages lie in a subcutaneous, granulomatous cyst which may contain a pale fluid. Rarely the cyst will contain a large amount of purulent discharge.

**DIFFERENTIAL DIAGNOSIS**

- No other disease causes the characteristic swellings on the back
- The differential diagnosis of posterior paralysis and anaphylaxis are discussed in detail under the respective headings of disease of the spinal cord and anaphylaxis
- The clinical signs of organophosphorus poisoning usually occur within 12–24 hours following application of the compound
- Posterior paralysis due to destruction of the larvae in the epidermal space usually occurs approximately 72 hours after application of the organophosphorus insecticide

**TREATMENT**

**Organophosphorus compounds**

Organophosphorus insecticides kill migrating larvae and can be applied by spray or a pour-on technique, by individual oral dosing or by mixing in the feed. They are highly effective, but unless used in strict accordance with the recommendations of the manufacturer damaging side-effects may occur.

The time of their administration is regulated by the stage of larval development and their location within the host. Hence the timing varies with climate. The emphasis is to deliver treatment shortly after all eggs have hatched and larvae are small and their death releases the least amount of enzymes into the host system. If treatment is delayed until these larvae have reached their maximum size, the sudden release of large amounts of proteolytic enzymes causes tissue damage that results in severe swelling. This swelling and inflammation affect the function of the esophagus (*H. lineatum*) resulting in bolting or swelling around the spinal chord leading to hind quarter paralysis (*H. bovis*). Severity of the reaction also appears to be related to the number of larvae present. These insecticides are not effective against second and third instars within the subcutaneous cysts.

Application in the form of a spray should insure that the skin is wetted by using a pressure spray (20–30 kg/cm²), and spraying the flat body surfaces such as the neck, back, shoulders, sides, and thighs. Use of a low pressure spray or wash should be followed by vigorous use of a curry comb or brush. Pour-on applications should be made carefully along the midline in a thin stream which penetrates the hair coat.

Although these compounds disappear very quickly from tissues, recommendations are that they should not be administered to milking animals, and beef animals should not be slaughtered for at least 60 days after dosing. Milking cattle with back lesions can be treated with derris dust (containing rotenone) but this must be brushed in vigorously or sprayed under pressure so that the material penetrates the larvae.

Toxic effects of organophosphates have been described elsewhere. The pitfalls in their use in warble control are related chiefly to the time of administration.

**Macrocyclic lactone compounds**

All larval stages of cattle grubs are very sensitive to these endectocides. Their widespread use in nematode control programs plays a major role in controlling warble flies. They remain effective for about 4 weeks.

**Manual removal**

When small numbers of cattle are affected with relatively few warble grubs, manual removal of the larvae is practised. Incomplete removal or breaking the larvae during removal may cause a severe systemic reaction. This reaction and the one which sometimes occurs after systemic treatment of cattle infected with warble fly have been ascribed to anaphylaxis. However, there is evidence that it is due directly to toxins liberated from dead warble maggots and that phenylbutazone may control this toxin. The clinical signs include dullness, salivation, lacrimation, dyspnea, wrinkling of skin on the side of the neck, and edema under the jaw.

**CONTROL**

While rotenone has been used successfully to kill the larvae in the subcutaneous tissues in the back, this technique does not prevent damage to the hide and has been largely superseded by the use of organophosphate insecticides and the macrocyclic lactone endectocides. In general, systemic treatments are given in the autumn (between September 15 and November 30) and in the spring after March 1.

Warble fly has been eradicated in Norway, Sweden, Denmark, Malta, Ireland, and Great Britain. Eradication programs have commenced in France. A joint Canadian–US study using sterile male *Hypoderma* species eradicated these species from the test area, but the difficulty of mass producing flies, in the absence of an in vitro rearing system, makes this technique impractical for large scale warble fly control.

Vaccination of cattle using crude larval extracts has reduced both the number of warbles in the back and the number of larvae that could pupate. Results of vaccination studies with recombinant antigens have been variable, but show promise although there has been no commercial development.

**REFERENCES**

**Cutaneous myiasis**

Cutaneous infestation by fly larvae or maggots (known as myiasis) causes serious loss to the livestock industries across the world. Losses include mortality, increased morbidity and reduced production of meat, milk, and fiber. The disease is associated with larvae of flies in two major dipteran families, Calliphoridae and Sarcophagidae.

Two types of cutaneous myiasis can be distinguished: primary, in which the fly larvae are obligate parasites feeding on living tissues and secondary, in which the larvae feed primarily on necrotic tissues and only secondarily invade uninjured tissue. Clearly, primary myiasis...
is most significant to animal health and therefore the most costly, not only in terms of mortality, morbidity and reduced productivity, but in terms of cost of control. However, it may be difficult to differentiate primary from secondary myiasis because the larvae are superficially similar.

Three primary fly strike disease states, resulting from the activities of different species, are well known and described. Blowfly strike by calliphorids such as Lucilia cuprina and L. sericata is a major problem, particularly for sheep producers, in Australia, New Zealand, and Great Britain. The second group are the screwworms, Cochliomyia hominivorax (in the New World) and Chrysomya bezziana (in southern Europe, Africa, and Asia) which are of importance across the livestock species and result in great costs for control. The sarcophagid (flesh fly) Wohlfahrtia magnifica causes traumatic myiasis in a wide range of livestock species, but has most impact in goat and sheep production. This species occurs in southern Europe, particularly the Mediterranean and the steppe regions of the continent. Because of differences in the nature of the disease state and control practices for each of these three groups they will be dealt with as separate entities.

**BLOW FLY STRIKE**

The cost of blow fly control and production losses in Australia for 1985 have been estimated as $200 million. A review of blow fly strike in Australia has been published and is given here as a review reference. Blow fly strike is a very important cause of losses in sheep in most countries where large numbers are kept. In bad years many sheep may die (up to 30% of a flock) and the expense of controlling the flies and failure of wool to grow after recovery may be a serious strain on the local sheep economy. Merino sheep, especially those with heavy skin wrinkles, are by far the most susceptible breed.

**Clinical pathology** A clinical examination is all that is necessary. **Lesions** Most, malodorous areas containing active larvae. Predisposing diseases such as dermatophiosis, fleece rot, parasitic gastroenteritis, and footrot are easily identified. **Diagnostic confirmation** Clinical signs are diagnostic. **Differential diagnosis** Lice, sheep scab, screwworm fly infestations. **Treatment** Organophosphates, macrocyclic lactone insecticides, or cyromazine. **Control** Cyromazine or triflubenzuron protect for 10–12 weeks while organophosphates kill larvae and protect for 2–3 weeks. Breeding for resistance and control of predisposing diseases is important. Conduct mules operation on lambs at marking, cut tails to the correct length, institute a proper gastrointestinal nematode control program, and give a mid-season crutching to control breech strike.

**ETIOLOGY**

Despite there being a large number of species capable of causing the disease, grouped geographically below, there are two species that are the primary agents of blow fly strike: Lucilia cuprina and L. sericata.

- **Australia:** Lucilia cuprina, L. sericata, (Calliphora stygia, C. novica, C. augue, C. hilli, C. albifrontalis, Chrysomya rufacies, Ch. varipes)
- **New Zealand:** Lucilia sericata, L. cuprina, (Calliphora stygia)
- **Great Britain and northern Europe:** Lucilia sericata (Calliphora erythrocephala, C. vomitoria, Phormia terraenovae)
- **North America:** Phormia regina, P. terra-novae.

**LIFE CYCLE AND EPIDEMIOLOGY**

The primary agents of fly strike are obligate parasites. Lucilia cuprina is overwhelmingly important in the initiation of strike in sheep from Australia, and South Africa. L. cuprina was introduced to New Zealand in 1988 and fly strike is now a major disease in that country. In northern Europe the primary agent of fly strike is Lucilia sericata although there are some other minor species that have been reared from struck sheep. In sheep, the incidence varies widely depending largely on the climate, warm humid weather being most conducive to a high incidence. In summer rainfall areas fly strike may be seen most of the year, being limited only by dry winter conditions; while in winter rainfall areas it is usually too cold in the winter and too dry in the summer for outbreaks to occur. Under these conditions abnormally heavy summer or autumn rains may be necessary before an outbreak will occur.

The fly population

Primary flies are of particular importance as these initiate the strike and provide suitable conditions for subsequent invasion by secondary flies. These latter flies are not of economic importance but may infest wool matted with dried exudate or feed on necrotic tissue surrounding healing strike. In warm areas pupal development may continue throughout the year but as soil temperatures fall an increasing number of larvae fail to pupate and larvae may overwinter until the following spring. In the spring adult flies emerge and after one or two breeding cycles, numbers build up to a peak in summer. Numbers may remain high if climatic conditions are suitable, moisture being of prime importance, but may fall dramatically in hot dry conditions. An increase in numbers may occur again in the autumn.

All adult flies require carbohydrate and water, but females require protein for ovarian development. The flies are attracted to sheep that have undergone prolonged wetting so that bacterial decomposition of the skin has occurred. The association of fly strike with fleece rot, mycotic dermatitis, diarrhea, urine staining, and footrot is related to the excessive moisture deposited on the skin or to the production of serous exudates. Fractions of *Pseudomonas aeruginosa* infected fleece have been shown to stimulate oviposition.

*L. cuprina* deposit eggs in batches of up to 300, the actual number depending on the fly’s size and its ability to locate suitable conditions for subsequent development. Similarly, *L. sericata* deposit eggs in batches of approximately 200. The average female longevity in the field in Australia is about 2 weeks and females rarely live long enough to mature more than two or three batches of eggs. In the UK mean female longevity is shorter at 5 days.

The eggs hatch in 12–24 hours and the first instars feed on protein-rich serous exudate that has been provoked by bacterial damage or some other irritation. Larval mouthhooks and enzymes present in the saliva and excreta will further digestion of the skin. Large groups of larvae, particularly second and third instars, further damage of the skin which extends the lesion and insures a continuing supply of food. The second and third instars are 6–12 mm long, thick, yellow and white in color and move actively. Larvae reach maturity after approximately 72 hours. They leave the feeding lesion, fall to the ground, wander briefly and then burrow into the earth to pupate. The length of the life cycle is highly temperature dependent; it be completed in as little as 8 days but
may require up to 6 weeks in temperate regions such as the UK. Eggs and larval stages are highly susceptible to desiccation and mortality will be high if the relative humidity in the fleece falls below 60%. In temperate climates such as the UK, as photoperiods decline the larvae that have left the host, will burrow into the ground and cease development, thereby overwintering as mature larvae.

Several generations of primary flies are necessary before numbers are high enough to cause severe outbreaks and therefore warm humid weather must persist for some time before severe outbreaks occur. The incidence of body strike increases with the increase in the number of gravid flies and is positively correlated with rainfall, cloud cover, and rate of pasture growth. Other primary flies are not as effective as L. cuprina in initiating a strike, and in Australia at least 85-90% of all primary strikes are due to L. cuprina. Larvae of primary flies, other than L. cuprina, and secondary flies develop in carrion or in rotting vegetation and their main role is to invade and extend the primary strike. Ch. nuijifacies is the most important secondary fly in Australia. It requires higher temperatures than the other flies, is found later in the season and is the first to disappear as temperatures fall.

Detailed population models have been developed for the strike by Lucilia spp. in Australia and northern Europe and both have been used to predict onset of fly strike in sheep populations. The latter model has been extensively validated and is sufficiently accurate to establish an early warning system for alerting producers to the impending onset of fly strike and thus allowing well timed prophylactic treatments.

Distribution of fly strike in flocks is highly aggregated with a small number of sheep having high numbers of larvae in lesions, a moderate number of sheep with low numbers of larvae and the majority of sheep being unstruck. In part this is a result of the attractiveness of already struck sheep to ovipositing flies, although other factors such as innate attractiveness play a role.

Susceptibility of sheep
By far the most common site for fly strike is the breech: infestation occurs here because of soiling and excoriation by soft feces and the urine of ewes. Lush pasture, parasitic gastroenteritis and fleece length are predisposing factors but individual sheep are predisposed because of the conformation of this part of their anatomy. Excessive wrinkling of the skin on the back of the thighs and the perineum, a narrow perineum and crutch and an excessively long or short tail favor continual soiling of the area and encourage 'crutch or breech strike' or 'tail strike'. Less common sites for infestation are around the prepuce ('pizzle strike'), on the dorsum of the head when there is excessive folding of the skin ('poll strike'), and along the dorsum of the body ('body strike') in wet seasons when fleece rot or dermatophilosis is common. Sheep grazing on tall, dense pasture are commonly affected by body strike because of the way in which the wet plants keep the fleece on the lower part of the body wet. Wounds, especially castration incisions, docking wounds and head wounds on rams caused by fighting, are also likely to provide good sites for blow fly strike. Young sheep are more susceptible.

PATHOGENESIS
The first instars feed on the exudate produced by the bacterial infection on the skin, but the larvae also produce excretory/secretory enzymes which may cause some skin degradation after egg hatch and provide soluble molecules on which the first instars can feed. Later instars can cause severe skin damage to provide themselves with food. Larvae may also migrate from the original area of strike, along the surface of skin to establish additional focal lesions.

Many primary strikes remain small and are unnoticed by the farmer. Such covert strikes may outnumber overt strikes and are important as a source of future generations of flies. Once the initial strike is made, the site becomes suitable for the secondary flies that now invade and extend the lesion. The effects of strike include toxemia due to absorption of toxic products of tissue decomposition, loss of skin and subsequent fluid loss, and secondary bacterial invasion.

CLINICAL FINDINGS
Individual sheep may be 'struck' at any time provided they are in a susceptible condition. Massive outbreaks tend to be confined to periods of humid, warm weather and are therefore in temperate areas usually limited in length to relatively short periods of 2-3 weeks, but in sub-tropical areas characterized by summer rainfall severe strikes may occur over many months.

The clinical effects of 'blowfly' strike vary with the site affected but all struck sheep have a basic pattern of behavior caused by the irritation of the larvae. The sheep are restless, moving about from place to place with their heads held close to the ground and they become anorexic. They tend to bite or kick at the 'struck' area and continually wriggle their tails.

If the area is large there is an obvious odor and the wool can be seen to be slightly lifted above normal surrounding wool. The affected wool is moist and usually brown in color although in wet seasons when fleece rot is prevalent other colors may be evident. In very early cases the maggots may still be in pockets in the wool and not yet in contact with the skin. When they have reached the skin it is inflamed and then ulcerated and the maggots begin burrowing into the subcutaneous tissue.

Three days after the primary oviposition feed intake is reduced, rectal temperature rises to about 42°C (108°F) and pulse and respiratory rates increase. Some sheep may die. The wool may be too hot to handle as a result of the inflammation caused by the mass of maggots that can be seen when the wool over the strike is opened. When primary strikes are invaded by secondary flies, particularly Ch. nuijifacies, the affected area is extended and the maggots may burrow deeply into the tissues. Affected sheep may lose their fleece over the affected area and may suffer a break in the remaining fleece. Tracts of discolored wool may lead to other affected areas of skin. As the struck area extends a scab forms over the center, the wool falls out and the maggots are active only at the periphery.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS
A clinical examination is all that is necessary to make the diagnosis but identification of the flies responsible may be important if epidemiology is being considered. Identification of larvae should be carried out by a specialist. Molecular techniques for accurate identification are available from specialists. Preservation of the larval stages is critical to these techniques and larvae should be rapidly frozen or preserved in 70% ethanol. Fly trapping may not correlate with larval findings as not all flies are equally attracted by commonly used baits.

DIFFERENTIAL DIAGNOSIS
Attention will be drawn to affected sheep by their foot stamping, tail twitching, and biting at the affected part. Affected sheep can easily be diagnosed by finding the moist, malodorous, maggot-infested area. Many covert strikes may be present without producing clinical signs. Predisposing diseases such as footrot, wound infections, dermatophilosis and diarrhea resulting from parasitic gastroenteritis are usually easily detected and maggot infestation is indicated by matting of the wool and discoloration.

TREATMENT
A local dressing containing a larvicide and an antiseptic is applied. The prevention of reinfections is also an important aim and as repellents have been largely unsatisfactory, it has become apparent
that the larvicide in a suitable dressing must be one with maximum retention in the treated area. Modern dressings usually contain organophosphate insecticides but most products do not kill all the organophosphate resistant larvae and some perform poorly even against susceptible larvae. Variations in effectiveness with the same compound sold by different companies is probably related to formulation. Ivermectin at 0.03 mg/kg applied by hand jetting is highly effective in killing all larval stages. Powder and liquid dressings containing diazinon, tetrachlorfenvinphos, propetamphos, and ivermectin are most generally favored.

Cyromazine, an insect growth regulator, is now widely used. It is particularly active against second and third instars, but is slow-acting and so live larvae may be seen in the fleece for some days after treatment.

**CONTROL**

Practical control of crutch strike in extensive farming areas depends on the use of the Mules operation to extend the bare areas around the perineum and tail, good worm control to prevent contamination of the perineal region, correct tail length and a midseason crutching. Control of strike in other situations is based on insecticidal treatment and treatment of wounds as they occur. Under conditions of extensive sheep raising, such as occur in Australia and South Africa and where climatic conditions are conducive to the development of the disease, the control of blow fly strike is a major undertaking and an extensive bibliography on the subject is available. Only a summary can be presented here.

The subject can be divided into three phases: reduction in fly numbers; prediction of fly waves followed by prophylactic crutching and application of larvicides; and reduction in susceptibility of sheep.

**Reduction of fly numbers**

Reducing the fly population has been of limited value as there are usually enough flies present to strike all susceptible sheep if suitable conditions are present. However, if the primary fly responsible for initiating strikes can be controlled the importance of secondary flies is greatly reduced. The measures used include trapping, early treatment of clinical cases and the proper disposal of carcasses and wool waste. Biological control by the use of insects parasitizing blow flies has been generally unsuccessful. Trapping, provided the traps are carefully looked after and satisfactory baits are used, can reduce the number of blow flies. Recent work with synthetic attractants have shown reduction of strikes by up to 55%, which suggests this approach will make a good adjunct to the overall fly management practices.

**Prediction of fly waves**

Sporadic cases of body strike may occur in sheep at any time and cannot reasonably be prevented, but if the environmental circumstances conducive to high fly populations and high susceptibility of sheep are recognized fly 'waves' can be predicted and short-term prophylactic measures taken. Warm, showery weather extending over several weeks allows several generations to be completed and sufficient flies to be available to cause an outbreak of strike. Once sufficient flies are present, an outbreak of cutaneous myiasis may occur whenever the sheep become susceptible. Warm humid weather, rain over 2–3 days, or grazing in long wet grass, may provide suitable conditions for the sheep to become susceptible to body strike. Sheep with yellow fleece, i.e. high suint content, comprised of pointed, thin staples less tightly packed and with a low wax content, would be most susceptible. Measurement of simple fleece values has been suggested as a means of predicting the susceptibility of flocks to fleece rot and fly strike. Sheep with long fleeces are more susceptible and the time at which shearing is carried out may exert an influence on the frequency and severity of outbreaks.

Outbreaks of breech strike will occur if the sheep have diarhoea, or if ewes have urine splashing off the breech area because the tails are too long. If an outbreak is predicted or has begun, 'crutching' and the prophylactic application of larvicides will reduce the severity of the infestation. 'Crutching' refers to clipping of the wool around the breech or crutch of the sheep to avoid it becoming wet with urine and faeces and providing a focus of attraction for flies. It is carried out routinely before lambing and immediately prior to a strike wave but provides protection for no more than 6 weeks. All the wool from above the tail, to the posterior aspect of the thighs and down to the hocks, must be removed. Because of the labor and loss of wool involved most sheep farmers depend on prophylactic dressing with a larvicide.

Predictive models incorporating climatic and production components have been developed in the UK. These are used to give producers warning of impending fly strike (see above).

**Treatment and prevention**

Prophylactic treatment with a larvicide has been a major part of blow fly control for many years but the preparations used and the methods of their administration have undergone many important changes. The triazine, Vetrazin, gives 8–10 weeks of protection and can be applied by jetting, as a pour-on or as an intraruminal slow-release bolus. Triflubenzuron, another insect growth regulator, also gives good protection. Their action is specific to dipteran larvae. It should be noted that they are slow to kill as they affect the development of the subsequent life cycle stage. Diazinon, tetrachlorfenvinphos, propetamphos, fenthion ethyl, coumaphos, and other organophosphorus insecticides are widely used, but the period of protection gained by their use has markedly declined as the resistance to these compounds has increased. Further, the organophosphorus insecticides may be degraded by *Pseudomonas aeruginosa*. However, most fly waves are of short duration, and if the insecticide is applied thoroughly at the time an outbreak commences, these compounds may still give sufficient protection to minimize losses.

Three avermectins and the synthetic pyrethroids act as oviposition suppressants. Deltamethrin is more active than the avermectins but the avermectins also produce significant mortality in the adult flies. They can be applied to the fleece as pour-ons or by spray races to prevent egg-laying.

The methods of application include dipping, jetting, and tip spraying. Dipping has the advantage of thorough wetting but requires high equipment and labor costs. Jetting is still recommended for crutch strike and if the jetting piece is combed through the wool from the poll to the rump with the solution at high pressure (500–900 kPa), good control of body strike will also be achieved. Tip spraying, which is the deposition of a higher concentration of insecticide onto the tip of the fleece, is only of use with dieldrin or aldrin as it
relies on the ability of these compounds to diffuse down the wool fibers. The latter compounds are now banned in most countries. Tip spraying is not effective with organophosphates.

It is recommended that sheep should be treated early in the spring. This protects sheep against the early season strikes, many of which are covert, and prevents the build-up of fly populations in spring and early summer which leads to outbreaks.

Reduction in susceptibility of sheep

The primary method for reduction of sheep susceptibility to fly strike is the Mules operation. This technique, originally developed to remove the wrinkled region of the breech where larval development is most prevalent, is now practiced in the recently established codes of practice. Other management practices are essential to reduce the impact of fly strike. The technique is still recommended in the recently established codes of practice. Other good management practices are essential for control of fly strike. These include management of gastrointestinal nematodes to prevent scouring, tails cut to the correct length and a midseason crutching to reduce soiling that predisposes animals to fly strike. Pizzle strike will be reduced by use of testosterone implants and by pizzle dropping (surgical separation of the preputial sheath from the belly) although this procedure may cause some difficulty at shearing unless the shearers are warned. Rimming (shearing of the pizzle area) will give 6–8 weeks protection. Fleece rot occurs most commonly on the withers of sheep, and the conformation that allows accumulation of moisture and the development of fleece rot and fly strike have been shown to be hereditary.

The modified Mules operation is best performed at marking (tailing and castration) as the lambs heal more quickly and suffer little, if any, setback in growth. Further, minimum death rates due to fly strike and maximum wool weights are obtained when sheep are mulesed as lambs. The technique has been developed extensively in Australia and is not described in detail here. In the hands of an experienced technician the time required to improve the perineal topography need be no longer than 1–2 minutes. The improvement is permanent and reduces crutch strike by 80–90%. Mulesing is accompanied by some pain, but current data unequivocally establish the positive health and welfare benefits conferred upon sheep in the Australian environment.

The protection gained by mulesing surpasses that afforded by breeding and is immediate and permanent.

The Mules operation is often supplemented by including a tail-strip operation in which a thin strip of woolled skin is removed from each side of the tail to above its butt. This results in a reduction of the amount of wool on the tail and less crutching as well.

Since the introduction of elastic rings for castration and removal of the tail, a tendency has developed to remove the tail at the butt. This allows wool to grow in around the anus where it may become soiled and struck and, when combined with the Mules operation which slightly everts the vulva, has caused a dramatic increase in carcinomas of the mucocutaneous junction in the vulva. Tail striping is important when tails are left at the longer recommended length, that is to the tip of the vulva. Docking so that the tail is of the correct length and so that a flap of ventral wool-less skin is left to seal over the stumps is important. The latter can be effected by pushing the skin back with the back of the docking knife before severing the tail.

Removal of the wool and skin wrinkles from the breech of sheep by surgical means or by selective breeding reduces the susceptibility of sheep to crutch strike and when combined with:

Alternatives to mulesing are seen as highly desirable, but remain elusive. A breeding program aimed at the selection of stock that predisposes animals to fly strike. Vaccination of sheep with proteases and extracts of peritrophic matrix from the larvae causes retardation of larval growth and in some cases leads to larval mortality. In practice it is difficult to envisage sufficient antibody being secreted through the skin to protect against the initial strike. However, it could reduce the number of third instars leaving the sheep and reduce subsequent fly numbers. Enhanced approaches utilizing recombinant proteins delivered cutaneously have shown additional promise. Vaccination against Ps. aeruginosa to protect against fleece rot and the likelihood of body strike has given encouraging results.

SCRWORM (COCHLIOMYIA HOMINIVORAX AND CHRYSOMYIA BEZZIANA)

Cutaneous myiasis associated with the screwworm maggots has been a cause of great financial loss in livestock in the western hemisphere, Africa, and Asia. Deaths may be heavy in groups of livestock which are at range and seen infrequently.

Etiology Cochliomyia hominivorax in the New World (New World Screwworm) and Chrysomya bezziana (Old World Screwworm) in Africa and Asia.

Epidemiology Eggs laid in fresh wounds. Fleas most active at 20–30°C. Disease spread by dispersal of flies or transport of infested animals.

Clinical signs Larvae invade the tissue producing characteristic large lesions containing mature larvae and foul smelling brown exudate.

Clinical pathology Not applicable.

Lesions Deep wound containing foul smelling brown material and third instars.

Diagnostic confirmation Rows of spines are present on the anterior part of each segment of the third instar.

Differential diagnosis No other disease causes such lesions.

Treatment Ivermectin 0.2 mg/kg subcutaneously kills many larvae and provides protection for 16–20 days. Other insecticides used as gels or ointments twice weekly are also effective. Doramectin subcutaneously.

Control Eradication has been achieved in North and Central America by the mass release of sterile males. Chemical attractant baits will reduce the prevalence of flies and strikes. Breeding and management procedures such as castration and shearing should be carried out in the cold weather.

Etiology Larvae of the flies Cochliomyia hominivorax and Chrysomya bezziana cause myiasis or 'screwworm disease' of animals. The flies are typically blow flies, C. hominivorax (New World Screwworm) being blue-
green with an orange head; *Ch. bezziana* (Old World Screwworm) is of similar coloring. *C. hominivorax* occurs in the Americas, *Ch. bezziana* in the Persian Gulf, Africa, and Asia. The occurrence of *Ch. bezziana* in Papua New Guinea provides a constant threat to livestock on the Australian mainland. A similar fly is *Callitroga (Cochliomyia) macellaria* which is not a true 'screw-fly' in that the larvae feed only on carrion or necrotic tissues.

**EPIDEMIOLOGY**

The screwworm maggots are obligatory parasites with no host-specificity. Thus, all domestic and wild, mammals, marsupials, and birds are potential hosts. Females are attracted to fresh wounds where they will oviposit. The navel of a newborn animal is a favored site, but fresh accidental or surgical wounds, such as those produced by castration, docking, and dehorning, are readily infested. Wounds which have already been infested are markedly attractive to the flies because of their odor. In bad seasons the flies will lay eggs on minor wounds such as areas of excoriation, tick bites, running eyes, peeling brands, and on the perineum soiled by vaginal and uterine discharges in animals which have recently given birth. Injury is not necessarily a prerequisite for screwworm strike in sheep, which can be struck in the intact intraorbital fossa and vulva. Wool loss and tenderness may occur and the remaining fleece may be stained.

The development of the fly is favored by hot, humid weather. The optimum temperature range for *C. bezziana* is 20–30°C (68–86°F). Below this the flies become sluggish and at 10°C (50°F) and below the flies will not move. Temperatures above 30°C (86°F) can be tolerated provided shade is available. *C. hominivorax* is active all year in areas where temperatures exceed 16°C and disperses rapidly from these areas as the temperature increases in the neighboring colder areas. The disease can be spread either by migration of flies or their carriage in livestock ships or commercial aircraft, by shipment of infested cattle or other livestock, and by movement of affected wildlife. The mean distance that *Ch. bezziana* can travel and deposit eggs is 11 km. The maximum distance is 100 km, but long distances are probably wind assisted. In the new environment the flies may die out if the climate is unsuitable or persist to set up a new enzootic area. Persistence of the fly in an area may depend upon persistence in wildlife or in neglected domestic animals, although the latter do not usually survive unattended for more than about 2 weeks.

In many enzootic areas it is common for the fly to persist in neighboring warmer areas during winter, returning to its normal summer habitat as the temperature rises. This pattern is exemplified by the introduction of screwworms into the southeastern United States in 1933 where they had not previously occurred. The flies died out in most areas in winter but persisted in southern Florida. In succeeding summers migrations of flies northwards caused outbreaks. The disease has since been eradicated from the area.

The disease is of importance in tropical and subtropical areas of Africa, Asia, North and South America, especially Central America, the Caribbean islands, Mexico, and American states bordering on Mexico. The prevalence of the fly in enzootic areas places severe restriction on the times when prophylactic surgical operations can be carried out.

The potential worldwide geographical distribution and abundance of *Ch. bezziana* has been assessed using a computer program. The differences in the observed global distribution and the potential predicted distribution indicate the areas at risk of colonization.²

**LIFE CYCLE**

The screwworm flies have a typical fly lifecycle with eggs, three larval instars, and a pupal stage. Females lay 150–500 white eggs in shingle-like clusters at the edges of fresh wounds. Larvae hatch in about 12 hours and penetrate the tissues surrounding the wound. The larvae preferentially feed on fresh, living tissue which is digested by regurgitation of a wide variety of salivary enzymes. Oviposition by other screwworm flies is encouraged by the presence of larvae already in the wound. The larvae feed as a group and at their time of maturation will have created a deep lesion 10–12 cm in diameter. Larval development is complete in 5–7 days, after which they leave the wound and fall to the ground. These mature third instars burrow into the upper soil layers and pupate. On the ground, pupal development is highly temperature dependent requiring from 3–60 days. Emerging flies commence egg-laying in about 1 week, having completed the life cycle, under optimum environmental conditions, in less than 3 weeks. There may be 15 or more generations per year.

The temperature sensitivity of the pupal stage, which is unable to survive freezing for more than short periods, limits the distribution of this parasite. As with all flies pupal development is highly temperature regulated. The screwworm pupal development is inhibited at soil temperatures below 15°C (60°F). Temperatures below this point for more than 2 months cause death of the pupa. Thus the occurrence of the disease is limited to warm climates.

Pupae are also affected by the moisture content of the soil. The emergence of adults is reduced when the moisture content is more than 50%, while temporary floods can drown pupae.

**PATHOGENESIS**

Following invasion of the wound a cavernous lesion is formed, characterized by progressive liquefaction, necrosis and hemorrhage. Anemia and decreased total serum protein results from hemorrhage into the wound. Secondary bacterial infection, toxemia, and fluid loss contribute to the death of the animal. Surviving calves frequently develop infectious polyarthritis.

**CLINICAL FINDINGS**

The young larvae invade the nearby healthy tissues vigorously and do not feed on necrotic superficial tissue. A profuse brownish exudate, composed of larval excreta, and host fluids, pours from the wound and an objectionable odor is apparent. This is highly attractive to other flies and multiple infestations of a single wound may occur within a few days. The resulting tissue damage may be so extensive that the animal is virtually eaten alive. Affected animals show irritation in the early phase of the infestation and by day 3 show pyrexia. Animals do not feed but wander about restlessly, seeking shade and shelter.

**CLINICAL PATHOLOGY**

It is imperative to differentiate screwworm infestation from infestation with other fly larvae. The appearance and smell of the wound are significant but careful examination of the larvae is necessary to confirm the diagnosis. Mature larvae are 1–2 cm long and pink in color; they are pointed anteriorly and blunt posteriorly; two dark lines are visible reaching from the blunt posterior to the middle of the body and they have rows of dark fine spines on the anterior part of each segment. Specimens forwarded to a laboratory for identification should be preserved in 70% alcohol.

**NECROPSY FINDINGS**

Superficial examination of infested wounds is usually sufficient to indicate the cause of death.

**DIFFERENTIAL DIAGNOSIS**

The presence of maggots in the wound is usually apparent. It is important to differentiate them from blow fly larvae as described above.

**TREATMENT**

Affected wounds should be treated with a dressing containing an efficient larvicide and preferably an antiseptic. The larvicide should be capable of persisting in the wound for some time to prevent...
reinfestation. A number of proprietary preparations and some of the newer insecticides have been compared. \(^2\) Lindane 3% and coumaphos 3% were the most effective but fenchlorphos 2.5%, diazinon 15%, chlorfenphos 0.05% and fenithion-methyl 0.2% were also very efficient. Stirofos (15%) and dichlorvos (20%) give season-long protection in the ears of cattle against *C. hominitorax* and *Amblyomma maculatum*. \(^4\) An ointment or gel base is preferred so that as much of the active ingredient as possible is left in the site. It should be liberally and vigorously applied with a paint brush to insure that larvae in the depths of the wound are destroyed. To avoid reinfestation in extensive lesions or in bad seasons the treatment should be repeated twice weekly.

When large numbers of animals are affected and individual treatment is impractical, spraying with a 0.25% solution of coumaphos, chlorfenphos, or fenchlorphos, using a power sprayer, is recommended. The spray is directed forcibly into wounds and, except for young calves, applied generally over the body to provide protection for about 2 weeks. Young calves may show signs of toxicity if sprayed too liberally and application should be restricted to the belly. These sprays can be used to protect animals which are not infested but are exposed to considerable risk or are to be shipped to free areas. In the latter situation duts are also available if spraying is undesirable in cold weather. A pyrophyllite dust containing 5% coumaphos and 2% mineral oil is effective as a protectant if applied at the rate of 60-180 g per animal. Residual protection lasts for 3–7 days.

Thirteen acaricides, commonly used for *Boophilus microplus* control, have been tested against *Ch. bezziana* larvae. While they are not sufficiently active to use as a primary treatment, their continued use for tick control would reduce screwworm populations.

Ivermectin 200 mg/kg given subcutaneously kills all *Ch. bezziana* larvae up to 2 days old and many older larvae. It provides residual protection for 16–20 days. Bull calves treated with ivermectin at the time of castration were completely protected against strike. \(^5\) A preliminary study showed that closanol at 15 mg/kg body weight was effective with a residual protection of 8–15 days. \(^6\) Doramectin 200 mg/kg subcutaneousy caused complete expulsion of *C. hominitorax* larvae within 8 days. \(^7\) Prophylactic use of ivermectin and doramectin significantly reduced occurrence of screwworm strike in cattle. \(^8\) Fipronil had a prophylactic effect, reducing occurrence of screwworm infestations in cattle and providing efficacious treatment in those that did become infested. \(^9\)

**CONTROL**

The eradication of screwworm by genetic means, chemical control, trapping techniques and lures, and dispersal of flies has been reviewed. \(^10\) In an enzootic area the incidence of the disease can be kept at a low level by the general institution of measures designed to break the life cycle of the fly. Surgical procedures should be postponed where possible until cold weather. In the warm months all wounds including shearing cuts must be immediately dressed with one of the preparations described under **TREATMENT**. All range animals should be inspected twice weekly and affected animals treated promptly. Infestation of fresh navels is common and newborn animals should be treated prophylactically. If possible the breeding program should be arranged so that parturition occurs in the cool months. The routine use of ivermectin for internal parasite control provides protection for about 2 weeks. \(^3\)

In the United States, the Caribbean, and central America an eradication program has been successfully carried out against *C. hominitorax* using the sterile insect technique (SIT). Huge numbers of pupae are mass reared on semi-artificial media and exposed to the sterilizing effects of cobalt 60. The resulting sterile male flies are released over large areas, primarily by aerially drops, where they compete with wild males for available females which mate only once. *C. hominitorax* has now been eliminated from the United States, the Caribbean, and all of Central America, up to the Darien Gap in Panama. \(^11\) *C. hominitorax* appeared in Libya in 1988, apparently with a load of sheep transported from South America, but has been eradicated using sterile male flies from the USA. \(^12\)

Attractants may also be used to reduce the fly population. A chemical bait has been developed, and when combined with an insecticide forms a screwworm adult suppression system (SWASS) which reduces the fly population and the incidence of strikes. An examination of the efficacy of various methods of baiting showed that polythene sachets containing swim-lure 2, a pungent mixture of 11 chemicals, attracted flies (not *C. bezziana*) for at least 2 weeks and was as efficient as jar baits. \(^13\) This result needs confirming in a screwworm endemic country.

**REFERENCES**

**WOHLFAHRTIOSIS (FLESH FLY)**

Cutaneous infestation by larvae of the sarcophagid fly, *Wohlfahrtia magnifica*, has become a major disease of domestic livestock, including birds managed extensively (e.g. geese) in the Mediterranean basin, eastern Europe, and western regions of China. \(^1\) The disease is particularly significant for sheep in these regions where it is more prevalent than strike by the calliphorid fly, *Lucilia sericata*.

Other species of this genus are known from North America, but they do not infest domestic species. They are predominantly reported from very young rodents and birds, although there are occasional reports from infants. \(^2\) Mortality of infested hosts tends to be very high.

**LIFE CYCLE AND EPIDEMIOLOGY**

Larvae of this species are obligatory parasites developing only in the living flesh of warm-blooded vertebrates. They are not host specific. Adults are typical for this group of flies, being dark gray in color with three distinct black stripes on the thorax where the wings are attached.

Female flesh flies, which are active during the warm parts of the day, deposit first instar larvae on the host, usually in small groups of 15–20. Each female may produce up to 170 larvae. Completion of the three larval stages takes from 5 to 7 days after which the mature third instars leave the lesion and fall to the ground where they pupate. Development of the fly within the pupa is regulated by temperature and may require between 7 and 21 days.

Larvae are usually deposited near small wounds (bites of blood-feeding arthropods are sufficient to attract the larvae), but the favored sites appear to be the genitalia. \(^3\) Irritation of the vulva associated with the use of vaginal sponges for estrus synchronization may be a predisposing factor in sheep.

Flies are active between April and October with several generations being produced. Little information is available on overwintering. Wildlife are suspected as being reservoir hosts, but little information is available on which are the most important.

**PATHOGENESIS**

Larvae have well developed mouthhooks which are used to abrade the skin surface and with the aid of a wide variety of salivary enzymes they quickly produce...
a dramatic lesion. Lesions increase in size as the larvae grow and require additional fresh tissue. Each animal may have one or more focal lesions, each packed with larvae. In severe cases several lesions may coalesce into one larger site.

Animals are often struck multiple times during a season, suggesting the absence of protective immunity. This adds to the impact of this disease as animals must be constantly monitored.

**CLINICAL PATHOLOGY AND NECROPSY FINDINGS**

A clinical examination is all that is necessary to make the diagnosis. Larvae can be distinguished from those of the screwworm or the strike flies by the presence of a large posterior cavity surrounded by a number of prominent tubercles. However, specific identification should be done by a specialist. Larvae should be preserved in 70% ethanol.

Affected animals are clearly stressed, showing restlessness and anorexia. Lesions formed at the vulva or prepuce are the most significant causing great discomfort and dysfunction. Lightly infested animals shown no impairment of productivity. Infested animals develop strong antibody responses to salivary secretions, particularly of the third instars.

**TREATMENT**

There are currently no products specifically registered for management of this disease. Evaluations of several drugs and treatment approaches have been made. Of particular interest is the equi-vocal results of trials with macrocyclic lactones. In sheep, ivermectin and moxidectin had no effect on existing infestations and no prophylactic effect or only short protection against early instars. In contrast, doramectin provided complete prophylactic protection for 21 days and significant reductions for 40 days. The pyrethroid, cypermethrin, was less effective.

The insect growth regulator diclinal has also been evaluated and shown to reduce prevalence of infestation in sheep. The reduction not only occurred in treated animals, but was seen in untreated herdmates possibly as a result of the overall reduction in fly numbers.

**REFERENCES**

**Ked and louse infestations**

Infestations with these insects cause irritation resulting in skin or wool damage. Blood loss may occur with some species.

**SHEEP KED (MELOPHAGUS OVINUS)**

This flat brown wingless fly, about 6–7 mm in length, was found in sheep throughout the world, but is now rarely reported in many countries. For example it wasn’t mentioned in a review of livestock ectoparasites of Europe and the Mediterranean, although anecdotal evidence suggests it may be present in isolated pockets associated with organic production. In Australia it is now rarely seen. The ked may transmit Trypanosoma melophagium and Rickettsia melophagi, harmless blood parasites of the sheep. Staining of the wool by the feces of the ked reduces its value and gives it a peculiar musty odor. Heavy infestations cause skin blemishes which are costly to the leather industry. Sheep in poor condition suffer most from infestations. Goats may also be infested.

**LIFE CYCLE**

Keds live their entire life cycle on the host. Adults of both sexes are blood feeders and although the degrees of infestation usually encountered cause only irritation with resulting scratching, biting, and damage to the fleece, very heavy infestations may cause severe anemia. Spread is generally the result of direct contact between hosts. A recent review suggests this exchange is primarily between dams and their offspring and that it is predominantly the newly emerged adults that migrate to new hosts. Larvae develop within the female one at a time and are deposited on the host as mature third instars which pupate within a few hours. The female ked lives for 4–5 months and may lay up to 10–15 larvae, so build-up of infection is slow. The larvae are attached to the wool fiber some distance above the skin and many larvae and pupae are removed at shearing. The young ked usually emerges in 20–22 days but this period may be prolonged for up to 35 days in winter. The complete life cycle takes 5–6 weeks under optimal conditions. Heavy infestations usually occur in winter months and they decline in the summer. The parasite is mainly seen in colder, wetter areas and infestations may be lost when sheep are moved to hot dry districts. Resistance is acquired in time and resistant sheep grow better and produce more wool.

A seasonal pattern of infestation occurs. Keds are sensitive to hot, dry weather and numbers decrease markedly over the summer. Populations increase slowly over the autumn and winter. While keds that have been dislodged from the host can live for up to 2 weeks if in mild moist conditions, most die in 3–4 days and probably do not play a part in reinfecting sheep.

**CONTROL**

At shearing a large proportion of adults and pupae will be removed. This can provide effective control on adult sheep particularly where a combination of hot conditions and a short fleece will kill most of the remaining keds. However, some may remain alive in protected places such as the ventral neck and breech regions and on younger stock. If treatment is carried out within the next 2–4 weeks eradication will be achieved as long as all sheep are included and the insecticide used has a residual protection longer than the time taken for the last pupae to hatch.

Keds are particularly susceptible to organophosphates and most of those used to eliminate lice will also remove keds. They can also be used in higher dose rates in pour-on applications. Diazinon used as a pour-on removed all keds and prevented re-establishment for 9 weeks. The synthetic pyrethroids are also active against keds; deltamethrin, cyhalothrin and cypermethrin are used. Cyfluthrin 2 mg/kg pour-on in sheep also eradicates ked and protects for 50 days. Amitraz will kill adult keds but has little residual action and is therefore usually combined with another compound to provide sufficient residual action to eliminate infections. Ivermectin given at the standard anthelmintic dose will also eliminate keds. Closantel which is mainly used against Haemonchus or Fasciola is effective against keds.

**REFERENCES**

**LOUSE INFESTATIONS (PEDICULOSIS)**

Lice infestations are common throughout the world. The species are host-specific and are divided into biting and sucking lice.

**Synopsis**

**Etiology** Species-specific sucking and chewing lice affecting all animals.

**Epidemiology** Transmission from host to host. Lice show a marked seasonal periodicity rising from low numbers after summer to a peak in the following late spring. Foot lice infested from pasture.

**Clinical signs** Irritation which causes rubbing, damage to the fleece or skin, and loss of milk production. Some species cause anemia. Foot lice cause stamiing.

**Clinical pathology** Hair loss may result from hypersensitivity.

**Lesions** Skin lesions due to rubbing, fleas have tufts protruding and lose their brightness.

**Diagnostic confirmation** Lice can be seen on careful inspection. Preferred site varies with host and species of louse.
**Differential diagnosis** In sheep must be differentiated from Psorergates, ked and Psoroptes infections. In other animals separate from allergic dermatitis.

**Treatment** Organophosphates, synthetic pyrethroids and macrocyclic lactones. 

**Control** Pour-on and injectable treatments control lice on cattle, horses, sheep, and pigs. Good husbandry practices, will reduce infestations. Plunge or shower dips used on sheep, all sheep should be treated and sheep must be thoroughly wetted. Treatment should follow shearing which removes many lice; sheep in short wool are also easier to wet.

**ETIOLOGY**

The important species are:

- **Cattle:**
  - Chewing lice - *Damalinia* (=Bovicola) *bovis
- **Sheep:**
  - Sucking lice - *Linognathus ovillus* (sucking face louse), *L. africanus*, *L. stenops* (sucking goat louse), *L. pedalis* (sucking foot louse)
  - Chewing lice - *Damalinia ovipus
- **Goats:**
  - Sucking lice - *Linognathus stenops* (sucking blue louse), *L. africanus*
  - Chewing lice - *Damalinia caprae*, *D. limbata*, *D. crassiceps
- **Pigs:**
  - Sucking lice - *Haematopinus suis
- **Horses:**
  - Sucking lice - *Haematopinus asini
  - Chewing lice - *Damalinia equi

**LIFE CYCLE AND EPIDEMIOLOGY**

**Sucking lice**

All life cycle stages are found on the host. Both sexes are obligate blood feeders, taking small meals from capillaries in the upper skin. Survival off the host is limited although some species, such as the foot lice of sheep, may survive away from the host for up to 2 weeks. Females lay 2–6 eggs per day which are attached to individual hair shafts. Eggs complete embryonation and hatch within 8–11 days of deposition. Lice have three nymphal stages, which bear a morphological similarity to the sexually mature adult stage. Each nymphal stage will take 2–4 days to complete. Louse development rate, at all stages, is highly temperature dependent and requires a narrow temperature range. Temperatures above 41°C and 46°C are lethal for eggs and adults, respectively, of *Linognathus vituli*. Optimal development takes place between 33°C and 37°C. Lice therefore show a seasonal periodicity with very low numbers in the summer when conditions are hot. Populations begin to increase with cooler fall temperatures, reaching maximum levels in late winter.

**Chewing lice**

All life cycle stages are found on the host. Lice feed on dead skin cells, hair, and oil secretions which they abrade from the surface using their chewing mouthparts. There may be some abrasion of the upper skin layers and there has been demonstration that sheep develop antibodies to salivary sections of *Damalinia (=Bovicola) bovis*. Sex ratios are highly female biased and there are suggestions that parthenogenesis occurs in some species. Females deposit <1 egg per day. Embryonation is completed in 7–10 days producing nymphs which molt three times before reaching sexual maturity. As with the sucking lice, development is highly regulated by temperature with a narrow range for optimal development and survival. Chewing lice can survive off the host for up to 2 weeks.

Transmission of both types of lice occurs by direct contact but inert objects such as blankets, grooming tools and harness may remain infective for several days. Sheep may become infested with foot lice from the pasture. Young pigs may become infected some 10 hours after birth. Newborn calves also rapidly acquire infestations from their dams.

**CLINICAL FINDINGS AND DIAGNOSIS**

**Sucking lice**

All species cause irritation of the skin and stimulate scratching, rubbing and licking leading to restlessness, damage to hair coat or fleece and hides and loss of milk production. These behavioral changes result in reduced efficiency, particularly in feedlot cattle.

Lice appear to be present on a large proportion of cattle, but measurement of their impact on productivity has produced equivocal results. It is often believed that infestation has little or no effect on weight gains and hematological values. However, there appears to be a synergistic effect between louse infestations and the presence of gastrointestinal nematodes that does have an impact on weight gain. Anemia is rare but has been described for heavy infestations of *H. eurysternus*. Treatment, however, may be warranted to reduce the damage to hides and prevent damage to fences and other fixtures. Hairballs may be present in infested calves due to continual licking.

The pig louse spreads swinepox and while weight loss may not occur, even with heavy burdens, some pigs develop an allergic dermatitis and the consequent rubbing leads to skin lesions.

Foot lice of sheep are believed to live on blood. Light infestations may not cause clinical signs, but moderate to severe infestations cause stamping and biting the affected parts. Lice cause goats to rub or to bite their coat, which becomes matted and damaged. Angora goats can damage the hair shaft and lose their coats. Signs of infestation are restless, hair loss, and decreased milk production. In horses *H. asini* is the more serious species as it removes blood and may cause some anemia.

**Chewing lice**

Sheep body lice cause irritation and rubbing. The wool loses its brightness, becomes cotted and more yellow. There is evidence that a pelt defect called cockle is associated with infestation with body lice. The quantity and quality of the fleece is reduced and losses up to AUS$3.20 per infested sheep have been measured.

Chewing lice on cattle also cause an increase in rubbing and licking which contributes to reduction of efficiency and damage to facilities. Hair loss has been attributed to this infestation, but it is a controversial association as many other causes are likely.

Diagnosis of lice on cattle and horses requires close visual inspection with particular attention being paid to known predilection sites. These include the head, the sides of the neck, the dewlap, the escutcheon, and tail switch. Effective diagnosis requires that hair be parted and skin examined at several locations at each of the predilection sites. Use of a supplementary light source and restraint of the animal is very helpful.

Chewing lice of cattle, sheep, and horses are recognized by their rounded head and light brown color. These lice are highly mobile and will move away from inspection sites. Their eggs are difficult to see unless on dark haired cattle or horses. Sucking lice are recognized by their gray or blue-gray color and their pointed head. They tend to remain fixed to the skin.

Chewing lice may congregate on the dorsal surface and flanks, while sucking lice are found on the head and in the long hair of the mane and tail but, in heavy winter infestations, lice may be found on any part of the body. In sheep with long wool, greatest numbers of *D. ovipus* may be seen on the midside, particularly the shoulders, from where they spread to the back and rump. After shearing, small residual infestations may be found on the ventral neck. Foot lice are usually found in clusters on those parts covered with hair, mainly on the lower limbs, but in heavy infestations they can be found in clusters.
above the hock, on the scrotum, in the belly wool, and more rarely on the face.

**TREATMENT AND CONTROL**

Self-grooming and grooming by headmates effectively regulates louse populations on most hosts, but the effectiveness is limited when hair coat or fleece become too long for the tongue surface to effectively remove the lice and eggs. Similarly, shearing is an important factor in reducing body lice populations on sheep. Between 30 and 50% of the population is removed with the fleece and those remaining are subjected to a more variable microclimate. Populations on sheep are at their lowest 30–60 days after shearing. Reversing temperature gradients as sheep move in and out of shade, and very wet conditions, will also reduce lice numbers.

Body lice of sheep are relatively easy to eradicate if a clean muster is achieved, if the sheep are thoroughly treated and reinfection is avoided. However, in practice, failure to eradicate commonly occurs due to the inability to thoroughly wet the fleece because of poor maintenance of dips or poor formulation of products, or because the lice are resistant to the chemical used. The most difficult problem when attempting to eradicate lice from flocks over a large area is the diagnosis of lice in lightly infested fleeces. Dipping clean sheep is wasteful but if lightly infested fleeces are not dipped the infestation will build up and may cause serious economic loss in the next year. Techniques have been devised to test for lice by digesting the wool and examining the residue for lice, but the delays inherent in such a system often mean that by the time the farmer obtains the results, the optimum time to treat sheep has passed. On-farm tests have been examined but none are yet sufficiently accurate.

Affected sheep can be effectively treated in a plunge or shower dip with organophosphate insecticides (diazinon, coumaphos, chlorfenvphos, carbofenthion, propetamphos), synthetic pyrethroids, or carbamates. The synthetic pyrethroids, cypermethrin and cyhalothrin, have been shown to be effective in sheep and goats. The synthetic pyrethroids, cypermethrin and cyhalothrin, have been shown to be effective in sheep and goats. They must be used immediately after shearing. A small proportion of sheep show irritation after application and some may show fleece damage. Further, most of the chemical that is applied remains in the tip of the fleece and grows out with the wool and so is not in contact with the lice.

The spread of synthetic pyrethroid following backline treatment of sheep is slower than in cattle and horses and takes some days to reach maximum concentrations along the midside. However, the ease of application, low capital outlay required, and the need for only one muster has led to rapid acceptance of backline treatments. It is important that the pour-on is applied along the spine from the poll to the tail. Failures to eradicate occur if the sheep are not cleanly shorn, and in large-bodied sheep with extensive neck folds which are difficult to shear cleanly. The presence of unshorn lambs, cot, or Dermatophilus-affecte fleeces, wrinkly sheep or inexperienced shearmen make backline pour-on application an inappropriate method. Heavy rain following application may also cause failure. Some lice remain alive for up to 6 weeks after backline treatment and so sheep are infective for this time. Jetting races have been used to treat sheep because of their ease of use and the speed with which sheep can be treated. However, none of the machines marketed in Australia is able to eradicate lice even from sheep with short wool.

The manufacturer's recommendations should be accurately followed, particularly when using shower dips. The most common cause of failure when using shower dips is poor maintenance of the pump so that insufficient volume of dip wash is applied from the overhead sprays. Blocked jets, incorrect speed of rotation of the top spray and leaving sheep in the shower for insufficient time are also common faults.

Infested long-woolled sheep can be jetted to reduce the population until the sheep can be shorn and dipped. Treatment of sheep in long wool leads to residue problems in the wool presented for sale. Every effort should be made to treat sheep properly in the first 2 weeks after shearing to insure eradication of lice and to present wool without insecticidal residues. Cyhalothrin has been shown to eradicate body lice from long-woolled sheep when applied by jetting at 20 ppm, but in field use eradication is rarely achieved. Phoxim 125 mg/L has also been reported to eliminate lice in long-woolled sheep, while 250 mg/L gave at least 4 months of protection against reinfection. An ivermectin 0.03% jetting fluid was reported to have high efficacy in treating lice in sheep with 3–9 months wool, but failed to eradicate. High concentrations of cyhalothrin (1500 ppm) and diazinon (36 000 ppm) in 100 mL applied to sheep has also proved effective but requires a practical method of application. No treatment is known that can eradicate lice from long-woolled sheep under field conditions. Following treatment of foot lice, sheep should be moved to a paddock that has been free of sheep for a month.

Treatment of goats has not been studied extensively and the treatments used on sheep and cattle are thought to be effective in goats. Lactating goats should not be treated.

Organophosphates (e.g. fenthion, famphur, chlorpyrifos, temephos, methidathion, fenchlorphos, phosmet) and pyrethroids (e.g. deltamethrin and flumethrin) have been used in pour-on application on cattle. While pour-on applications are easy to use, none will kill all lice; they are expensive compared with sprays if large numbers are to be treated, and in many countries they should not be used on lactating cows. Similarly, organophosphates (diazinon, coumaphos, ethion) and pyrethroids (cypermethrin) or combinations (bromophos-ethyl combined with chlorfenvphos) are used as sprays or dips for cattle. Macrocyclic lactone based products (ivermectin, moxidectin, doramectin and eprinomectin) are available as pour-on or injectable formulations for cattle and have shown excellent efficacy against both sucking and chewing lice. Persistence of activity is one of the exceptional benefits of these products.

Fenthion 2% has been widely used on horses in Australia with good results although coat color changes and, rarely, hair loss does occur. A single subcutaneous injection of 0.2 mg/kg ivermectin will remove sucking lice but is not completely effective against chewing lice. Moxidectin, a compound with ivermectin-like activity, performs similarly. Treatment of horses with a shampoo containing 1% selenium sulphide three times at 10 day intervals eradicated lice; most horses showed a marked improvement after treatment.

Sheep lice have been shown to quickly develop insecticide resistance and strains of *D. ovis* which are resistant to the chlorinated hydrocarbon insecticides are common in the United Kingdom, while strains of lice resistant to the synthetic pyrethroids have followed inappropriate backline use of these compounds. Resistance management strategies that involve rotational use of the various insecticide/parasiticide active ingredient categories should be adopted wherever practical. For example, if pyrethroid-resistant lice are present an organophosphate or macrocyclic based product should be used. Subsequent treatments should involve another change of compound class.

Treatments should be timed to coincide with the beginning of population growth (i.e. autumn or early winter). Extremely early treatments often result in spring outbreaks that result from very small residual populations on a few animals. When products with short residual activity
Tick infestations are of great importance in the production of animal diseases. In addition to their role as vectors of infectious diseases, as outlined below, heavy infestations can cause direct losses. Many are active blood feeders and may cause death from anemia. Some species cause tick paralysis and it is possible that other ticks may elaborate toxins other than those causing paralysis. Heavy tick burdens cause sufficient irritation and stress such that affected animals become anorexic which may lead reduced productivity. One tick, *Boophilus microplus*, is reported to affect in excess of 75% of the world cattle population. The economic impact has been estimated at $7 (US) per animal per year and in Brazil with the fifth largest cattle herd, the losses are estimated at $2 billion per year.

The life cycles of the ticks vary widely. Some species pass their entire life on one host, others pass different stages of the cycle on successive hosts, and others are parasitic only at certain stages. The eggs are laid in the soil and larvae attach themselves to a passing host on which they may develop through one or more nymphal stages before becoming adults. Adult females engorge on blood or lymph and drop to the ground to lay their eggs. One-host ticks are more easily controlled than those which pass part of their life cycles away from the host. A list of the single and multiple host ticks is shown in Table 28.1.

Although many ticks favor a particular host they are usually not completely host-specific and many parasitize a wide variety of animals. In the limited space available here the species are listed according to whether they cause worry only or transmit infectious diseases of large domestic animals.

For more detailed information on the transmission of infectious diseases and the biology and distribution of ticks the papers of Neitz and Théler should be consulted, while the role of ticks in disease is covered well by Sonenshine.

**Ticks causing paralysis**

Paralysis is not uncommon in young domestic animals which are heavily infested with ticks. A review lists 31 species in seven genera of ixodid ticks and seven species in three genera of argasid ticks as being implicated in tick paralysis. The most important species are given in Table 28.2. Details of the clinical syndromes are provided in Chapter 32. Recovery is usual in early mild cases if the ticks are removed but antiserum against some (e.g. *Ixodes holocyclus*) is available.

**Ticks which transmit protozoal diseases**

Ticks are the most important vectors of the protozoan diseases, the protozoan in most instances surviving from generation to generation in ticks by infecting their eggs. Where control of these diseases is to be undertaken it is necessary to know which ticks are vectors, how many hosts the tick parasitizes during a life cycle and which animals can act as host. Much of the information on these points is fragmentary and only a summary is presented in Table 28.3.

**Bacterial, viral and rickettsial diseases transmitted by ticks**

The transmission of diseases associated with these agents may be effected by means

---

**Synopsis**

**Etiology** Many species of ticks act as vectors of disease or cause death from anemia; others cause paralysis. Heavy burdens cause loss of production.

**Epidemiology** Life cycles vary widely both in the number of hosts required and the host specificity. Animals are infected by larval or nymphal stages on the ground.

**Clinical signs** Anemia, paralysis, tick fever, and tick worry.

**Clinical pathology** Ticks obvious on skin damage due to biting and rubbing, anemia. See other chapters for more detailed information.

**Lesions** Skin damage due to biting and rubbing, anemia. See other chapters for more detailed information.

**Diagnostic confirmation** Ticks easily found, should be identified to species.

**Treatment** Dipping, pour-ons and injectable acaricides.

**Control** Regular treatment at intervals dependent on the life-cycle of the tick, pasture spelling to destroy free-living stages, the use of resistant cattle and vaccination all play a part.

other than ticks. *Anaplasma marginale* can be spread by biting flies if large numbers are present when the animals are experiencing a heavy parasitemia. Outbreaks of anaplasmosis can also occur following the use of blood transfusions. The fertility of males also cause greater morbidity and mortality of production, anemia and death when they are present in large numbers. They also cause greater morbidity and mortality during periods of drought, as well as delays in fattening resulting in animals held longer before they can be sold. A list of ticks which have this effect on production but which are not known to cause paralysis or transmit infectious diseases in farm animals, is given below.

### Ticks which cause direct losses

Ticks cause damage to hides and loss of production, anemia and death when they are present in large numbers. They also cause greater morbidity and mortality during periods of drought, as well as delays in fattening resulting in animals held longer before they can be sold. A list of ticks which have this effect on production but which are not known to cause paralysis or transmit infectious diseases in farm animals, is given below.

**TREATMENT AND CONTROL OF TICK INFESTATIONS**

Four methods are now available to control ticks:

- Treating with acaricidal agents
- Pasture spelling
- Vaccination
- Use of resistant cattle.

Crude vaccines made from extracts of semi-engorged adult female *B. microplus* give effective immunity. Antibody destroys cells lining the tick's gut and allows blood to escape into the hemocoele, some ticks die and the fertility of those remaining is reduced by up to 70%. The fertility of males is also reduced. A recombinant vaccine based on a membrane bound glycoprotein Bm86 has been isolated and shown to be as effective as the native antigen, and to be effective against acaricidal resistant ticks. Its major effect is a progressive control in tick numbers in successive generations through a decrease in their reproductive capacity. Because the vaccine acts against an antigen in the tick's gut to which cattle are never exposed, they must be given booster injections at regular intervals.

This was the first recombinant parasite vaccine sold commercially and is marketed in Australia as Tickgard. A similar product, using the same antigen produced in a eukaryotic expression system, was produced in Cuba and has been trialed in other countries. A second antigen has now been added to the vaccine (Tickgard 2). This significantly enhances efficacy and does not impair the response to Bm86. Addition of a saponin adjuvant has greatly increased the efficacy of the vaccine.

Although vaccines offer long term control, they need to be used with pasture management, dips and tick resistant cattle as part of an integrated pest management control system. Certain *Stylosanthes* spp., tropical legumes, can kill or immobilize larval ticks and the use of these plants may simultaneously improve pasture quality and reduce the pasture contamination of larval ticks if high legume to grass ratios are achieved. *Brachystegia brizantha* has also been shown to be lethal to *Boophilus* larvae.
Integrated management of ticks requires the use of several complementary approaches to reduce populations below acceptable thresholds. One component of these strategies is the development of acarical pathogens that may augment other approaches such as vaccination and selective acaricide application. Fungal pathogens are under evaluation for use in this type of program, in particular *Metarhizium anisopliae* and *Beauvaria bassiana.*

### Choice of acaricide

Individual animals can be effectively treated by the application of any one of a number of acaricides applied either as a spray or by dipping. The choice of acaricide depends largely on three factors:

- The persistence of the compound on the skin and hair coat
- The likelihood of residues toxic to man appearing in the milk or meat
- Whether or not the ticks in the area have developed resistance to the particular acaricide.

The same criteria apply in control as in treatment except that cost becomes a limiting factor when large numbers of animals require frequent treatments and it is obvious in some circumstances that the effect of tick infestation on Brahman-cross steers is insufficiently great to warrant treatment. It is impossible to make specific recommendations on methods of application and the most efficient insecticide to use because these vary widely between species of ticks. However, whenever possible, treatment should be given systematically in a program based on the life cycle and epidemiology of the tick. A number of treatments may be used to control multiresistant strains and is likely to lead to resistance. Cyhalothrin also controls resistant strains and is used in plunge dips.

Bioassay results show lambdacyhalothrin to be as effective as cyhalothrin as a whole body spray, although the 1% pour-on was less than 50% effective. Resistance to all pyrethroids has been reported. Three pyrethroid acaricides have been shown to markedly reduce the hatching of eggs. Permethrin 0.1% or cypermethrin and cyfluthrin 0.05% could be useful in cleansing and disinfecting premises.

The organophosphates as a group are effective but resistant to many of them have appeared. Other drugs in current use include dioxathion, diazinon, carbofuran, coumaphos, ethion, bromophos-ethyl, chlorpyrifos, and phosmet. Pour-on applications of chlorpyrifos and phosmet have been tested but were not as effective as spray applications. Addition of acaricides to the feed has also been tried but has not been successful, while eartags impregnated with tetrachlorvinphos did not give satisfactory control and increased the risk of resistance developing to the drug. Ivermectin given subcutaneously gives satisfactory control of *Boophilus microplus*.
for 21 days following an initial lag period of 2 days. As little as 0.015 mg/kg per day gives complete control and raises the possibility of a slow-release subcutaneous implant. Two treatments of 0.2 mg/kg at 4-day intervals is considered satisfactory in cleansing cattle under field conditions. However, ivermectin may not be effective against *Ixodes ricinus* but a slow release bolus active for 90 days did give good control of a variety of ticks. If given topically 0.5 mg/kg was required to give the efficiency achieved by 0.2 mg/kg subcutaneously.

Moxidectin 200 mg/kg subcutaneously at 4-week intervals or 500 mg/kg as a pour-on along the back gives good protection against *B. microplus* resistant to organophosphorous insecticides and DDT, and each treatment gave a rapid knockdown effect on populations of buffalo fly after treatment. Doramectin 200 mg/kg is highly efficacious in removing *B. microplus* and preventing re-establishment. Closantel 22.2 mg/kg orally to cattle disrupted the life cycle of *Rhizophagus appendiculatus*; those that oviposited laid few eggs and most of these did not hatch. Few larvae or nymphs molted.

Ticks in the ear of horses should be treated by the insertion of a few drops of an oily acaricidal preparation.

Preparations vary in the duration of the protection they afford and local conditions of rainfall and tick population must be taken into account when determining the time intervals between spraying or dippings. A special case is that of young lambs which are exposed to tick pyemia. Sprays, dips, and ointments are too toxic and the most effective procedure is the application of a liquid emulsion cream containing the insecticide to the wool-less parts of the body. Chlorpyrifos 0.48 kg/ha markedly reduces the number of ticks on the pasture, but is too expensive for routine use.

Resistance to chemical acaricides has become a major issue for the effective management of one cattle tick, *Boophilus microplus*. In many cases cross-resistance between chemical families occurs, further complicating the use of rotational scheme aimed at managing the development and degree of resistance. The development of strains of this tick resistant to macrocyclic lactone has been reported.

**CONTROL AND ERADICATION**

In most countries all that is attempted is reduction of the tick population by periodic dipping or spraying. Complete eradication is extremely difficult because of the persistence of ticks, especially multihost ticks, on wild fauna, and the ability of adult ticks to live for very long periods away from a host. On the other hand, continuous treatment to restrain the tick population is highly conducive to the development of resistance, a problem which has become apparent in many tick areas. *Boophilus annulatus* was eradicated from the southeastern United States by a program of continuous dipping at short intervals of all livestock in the area. *B. microplus* was also eradicated from Florida by a similar procedure but 20,000 deer, the important alternate host in the area, had to be slaughtered. Concern has been expressed that deer and other wildlife species may threaten efforts to prevent *B. microplus* and *B. annulatus* becoming re-established in southern USA after they are introduced from Mexico. Attempts to eradicate other single-host ticks in other countries have not been generally successful.

Although both dipping and spraying are recommended for the control of ticks, complete wetting of the animals, which can only be effected by dipping, is essential if eradication is to be undertaken. This adds another impediment to eradication plans because of the cost of constructing proper dips and yards. When one considers that dipping may have to be carried out every 14 days for 15 months, that every animal in the eradication area must be dipped, and that a strict quarantine of the area must be maintained, it is obvious that eradication cannot be undertaken lightly. The use of pour-on applications, which allow a longer period between treatments, and of ivermectin, will necessitate a review of control and eradication techniques.

Measures other than the application of insecticides used in the control of tick infestation include burning of pasture, removal of native fauna, plowing of fields, and rotational grazing. So little is known of the bionomics of specific ticks in specific areas that these measures have been largely unsuccessful and it is impossible to provide details for their proper implementation.

In those areas where the epidemiology is known it has been shown that in regions with a cold winter the females stop laying eggs, and that the development of eggs is prolonged. This results in few larvae being available in the spring, and if repeated treatments are given at this time, pasture contamination will remain low for some months. In hot tropical areas where the required temperatures for tick breeding are always present, the dry period may cause mortality by desiccation.

Pasture spelling and rotational grazing have been shown to be capable of greatly reducing the tick population on farms in some areas. If cattle are placed on spelled pastures early in winter when the ticks are producing few or no progeny and then alternated at 4-monthly intervals, the tick population can be controlled with a markedly lower number of treatments. The practicability of the procedure depends upon a full-scale financial assessment of the increased weight gains relative to the costs of management. Duration of the spelling period varies between 2 and 3 months in summer to 3–4 months in the winter, but these intervals need to be determined for each district. In practice, pasture spelling is rarely used.

It is possible to reduce the impact of ticks and tick-borne diseases by the introduction of Brahman and Brahman-cross cattle which are more resistant than British breeds. The resistance has been shown to be largely acquired, and is mainly expressed against the larvae in the first 24 hours after attachment. In Australia the possibility that *B. microplus* might escape from its control area because of increased resistance to acaricides has been realized. For this reason a great deal of attention is being paid to the possibility of selecting cattle for tick resistance. In most tick-infested areas, cattle should have up to 50% *Bovis indicus* breeding, as this allows a reduction in the frequency of treatments. Penalties such as reduced liveweight gains, late maturity and poor temperament become evident when cattle have more than 50% *B. indicus*. With successive infestations cattle differ in their response to *Boophilus microplus*. Thus there is increased irritation and more lickings and a decrease in the number of ticks carried. Resistance to ticks has been shown to be heritable and can be increased by breeding from cows and bulls selected for resistance. Selection for tick resistance does not affect milk production.

Other special cases include *Otothius megginii*, the nymphs of which drop off to molt and lay eggs in protected spots, necessitating the spraying of buildings, fence posts, feed troughs, and tree trunks in feedlots where heavy infestations are most common. *Omithodorus* ssp. ticks are difficult to control because the nymphs and adults attach to feed for brief periods only. Where ticks which cause paralysis are common it may be necessary to apply an insecticide as a dust and dip at short intervals.

**REFERENCES**

**Miscellaneous flies, midges, and mosquitoes**

Although these insects differ quite markedly they are dealt with together because they exert similar deleterious effects. Their activity causes stress and induces behavioral changes and in many cases are important vectors for a variety of parasites and infectious diseases.

**STABLE FLIES**

The stable fly, *Stomoxys calcitrans*, has a cosmopolitan distribution, occurring in most countries. Other species, including *S. nigra*, occur in South Africa. *S. calcitrans* is about the size of a house fly, is gray in color. These flies are the most economically important species affecting confined livestock in North America. Flies rest on fences and structural surfaces in a characteristic head upwards position and can readily be recognized by the prominent, forward-directed, pointed proboscis between short palps. Stable flies of both sexes are blood feeders, attacking particularly horses, cattle, to a lesser extent pigs and people. Bites are quite painful and often bleed freely when fresh. The flies are intermittent feeders, spending only short periods on the host, while most of their time is spent resting on fences and building sides. Eggs are laid in high moisture areas of rotting hay or straw, along the edge of silage pits, on the edges of manure pack of feedlots and compost piles. Mature larvae leave the high moisture sites to pupate in drier sites nearby. Development times are regulated by temperature, with higher temperatures resulting in more rapid development. A complete life cycle will require 3–4 weeks in summer. In temperate climates flies exhibit a distinct seasonality with peak populations in mid to late summer. Larvae will overwinter in warmer areas of silage piles. The flies are highly mobile traveling up to 20 km in search of suitable hosts.

Feeding activity by the flies results in stress to the animals and reduced efficiency through reductions in feeding time. When large numbers of flies are present the animals will bunch to reduce biting rates. At high temperatures the bunching may result in cattle overheating. A localized sensitivity of the forelimbs of cattle may develop and result in the formation of intradermal blisters which coalesce to form bleeding sores. With very heavy infestations some deaths may occur. Populations can be assessed by counting the number of flies on the front legs of cattle. When the average number exceeds 5–10 per animal significant losses are occurring and population management is required.

*Stomoxys calcitrans* are mechanical vectors for anthrax, infectious equine anemia, bovine virus, diarrhea virus, and surra. They are intermediate hosts for the nematode *Habronema maia* which is reputed to be a cause of allergic dermatitis in horses in Japan.

Effective management of stable flies requires removal of high moisture, rotting organic matter from the environment. Edges of silage piles, manure, and compost piles should be kept dry and manure-contaminated bedding should be removed regularly. Insecticide treatments must be applied to all exterior surfaces (i.e. barn sides, fences, and exterior of feed bunks). Diflubenzuron 0.5 g/m² sprayed in a cow barn completely inhibited breeding of the house fly and stable fly. Spraying of fixtures and walls, particularly sunlit walls where the flies often remain unnoticed, with long-acting compounds such as tetrachlorvinphos, diazinon, crotoxyphos, and propoxur reduces infestations for 2 weeks or longer.

Application of insecticides or repellants directly on animals is generally impractical because of the short duration of efficacy. Low frequency of insecticidal application, when necessary, slows the development of insecticide resistance. Crotoxyphos and methoxychlor can also be sprayed onto cattle giving about 4 days of protection. Fenchlorphos can be used but requires daily spraying or daily or alternate daily wipe-on application for good control. Permethrin applied as a microencapsulated formulation gave longer protection than an emulsifiable concentrate. Affected horses can be treated locally with an analgesic cream, and if the irritation is severe they can be tranquilized with acetylpromazine.

**HORSE FLIES; MARCH FLIES OR BREEZE FLIES (TABANUS SPP); DEER FLIES (CHRYSOPS, HAEMATOPOTA, AND PANGONIA SPP)**

These large, robust blood feeding flies are widespread in both temperate and tropical regions. Only the females take blood meals, but the bites are savage and cause significant distress to large animals, particularly horses and cattle. These flies can act as mechanical vectors of diseases associated with viruses (equine infectious anemia, bovine leukosis, vesicular stomatitis, hog cholera), bacteria (anthrax, tularemia), and trypanosomases (surra). Eggs are laid on the leaves of plants growing in or near standing water. The larval and pupal stages occur in the water or mud and the life cycle takes 4–5 months to complete. The flies are active in summer and attack animals principally on the legs and ventral abdomen. Duration of activity can be relative short (i.e. 3–4 weeks), but stress on the animals can be very high during that time. Fly attacks lead to bunching of animals with the attendant likelihood of overheating and in some cases resulting in animals stampeding through fences. Control is difficult unless wet areas can be drained or livestock kept away from these areas where the flies are most active. Repellents have been used and are reasonably effective in horses subject to fly-worry. The use of o-diethyl toluamide (DEET) affords protection for only a few days and is costly, but its use in milking cattle gives increased milk yield and butter fat. Permethrin, a synthetic pyrethroid, used as a spray or as a dust on cattle and horses, killed 90% of flies for about 2 weeks after treatment. Synthetic pyrethroid impregnated ear tags give very little protection against these flies.

**BUFFALO FLIES; HORN FLIES (HAEMATOBIA SPP.)**

These small (6 mm) grayish flies have distinct geographical distributions, *H. irritans exigua* in Australia and Southeast Asia, *H. irritans irritans* throughout North and South America and Hawaii, and *H. minutu* in Africa. *Haematobia irritans irritans* is common in Europe where it causes few problems. This species was transported to North America in the late 1800s, where it rapidly established and spread. It has subsequently moved into South America where it has also become a major problem. They have similar life cycles and habits. Both sexes of these flies are obligate blood feeders, primarily attacking pastured cattle and water buffalo.
They do not survive off the host, other than for short periods. They are not known as vectors for any disease agents other than the nematodes *Stephanofilaria* spp. They cause significant reductions in productivity of pastured cattle through induction of stress, changes in grazing patterns and, in extreme cases, blood loss. Burdens of 200–500 flies will reduce weight gains of beef cattle (up to 14% reduction) and milk yield of dairy cows. Heavy infestations (over 1000 flies) can cause serious loss of condition and rarely, deaths. Control results in higher feed efficiency, increased growth rate and increased calf weaning weights.

The flies congregate chiefly on the withers, shoulders and flanks as well as around the horns and eyes. Flies take numerous (15–20) small blood meals per day. In North America feeding often takes place on the ventral midline and several 2–5 cm diameter feeding lesions are often observed. Zebu cattle are less affected by the flies than British breeds and although they may carry large populations of flies, they show fewer feeding lesions.

The flies are easily recognized by the way in which the wings are held at rest, slightly divergent and angled upwards away from the body. Adult flies stay on the host most of the time, unless disturbed. Females leave the host, as feces are passed, to deposit eggs around edges of the freshly deposited dung. Larvae develop within the dung pat, feeding primarily on bacteria. Development is regulated by environmental temperatures and the larvae are stimulated to enter diapause (arrested development) if temperatures become too low. Mature larvae exit the dung to pupate in the dry ground between two posts 4–5 m apart. Cattle quickly learn to use rubbers to dislodge flies and their coats become smeared with insecticide. Ethion 1% in fuel oil is commonly used against *H. irritans exigua* while coumaphos 1 or 2% has been shown to be effective against horn flies. Insecticide-impregnated ear tags attached to back rubbers and dust bags controlled horn fly for about 6 weeks, while feralaterle tags were still effective 18 weeks after application.

Eartags impregnated with organophosphorus compounds and synthetic pyrethroids have been widely used, but resistance has built up to levels that make this technique ineffective. Discontinuing the use of pyrethroid impregnated ear tags for one season does not allow substantial reduction in resistance to occur. Recent work reported that eartags impregnated with 20% diazinon gave 90–100% control of *H. irritans exigua* in dairy and beef herds and allowed better weight gains, but if continued will lead to resistance as resistance to diazinon has been reported in eastern Canada and in the United States. Eartags impregnated with compounds of both classes have been effective in managing increases in pyrethroid resistance. Current recommendations for use of impregnated ear tags note that tags should be applied to the cows (because they harbor the most flies and present the largest surface area for exposure to the insecticide) at the maximum recommended rate. While this is less convenient it helps to avoid one of the leading causes of insecticide resistance which is the dilution of the insecticide as it spreads from calves to cows. Flies can also be controlled by dipping, but this technique is rarely used solely for flies. Organophosphorus compounds have a residual protection of only a few days and products are combined with synthetic pyrethroids to extend the protective period. In areas where cattle ticks require regular treatment adequate control of flies may be gained incidentally, but if treatments are not effective cattle can be oversprayed with pyrethroids.

Macrocyclic lactone endectocides are highly effective against larval horn flies as well as larvae of face flies, stable flies, and house flies, often killing larvae for periods in excess of 8 weeks. However, in terms of practical control, where flies immigrate from surrounding herds, the duration of efficacy is not more than 2 weeks. In addition, the macrocyclic lactones generally cause significant reductions of non-target insects in the dung community, many of which are beneficial as they are natural enemies of the horn fly and buffalo fly. The various macrocyclic lactone products have differential effects on flies and other dung insects and it appears that moxidectin has the least impact.

Four-on formulations of pyrethroids are highly effective as evidenced by application of 1% cyfluthrin. Insect growth regulators (e.g. Diflubenzuron) applied as a bolus give 80% control of the immature stages of the face fly-horn fly in the manure for at least 20 weeks but reduced the number of dung beetles for 7 weeks. A 3% methoprene bolus was also active against flies but had no apparent effect on the dung beetles.

**HORSE LOUSE FLIES (HIPPOBOSCA EQUINA, H. RUFIPES, AND H. MACULATA)**

The horse louse fly, *Hippobosca equina*, is a common parasite of horses and cattle in many tropical countries. It is a flat, glossy, reddish-brown fly, slightly bigger than a housefly. These flies are blood feeders and live most of the time on the host, particularly on the perineum and between the hindlegs. Female flies deposit single mature third instars which pulate in dry humus; the puparia mature to adult flies. The flies appear to cause little annoyance in horses which are accustomed to them but horses experiencing them for the first time manifest fright and irritation. Being blood feeders they may act as mechanical vectors for infectious diseases. Topical spraying of susceptible areas of the body with chlorinated hydrocarbons appears to keep these parasites in check. Local application of 0.2% coumaphos solution quickly kills flies but only gives protection for 3 days. *H. maculata* was controlled for 1 year by mass application of 0.005% deltamethrin to cattle and horses.

**BITING MIDGEs**

These tiny flies (1–3 mm long) are members of the family Ceratopogonidae, the important genus being *Culicoides*. These flies are blood feeders and as such induce stress in hosts and can transmit infectious diseases such as bluetongue in sheep, horse sickness, ephemeral fever in cattle. They are also intermediate hosts for nematodes of the genus *Onchocerca*. Because of their importance as vectors of arboviruses, studies have been done on their feeding habits. Cattle and sheep are the most
common hosts attacked but some species also feed on birds or dogs. Hypersensitivity to the bites of *Culicoides brevitarsis* results in an allergic dermatitis (Queensland itch or sweet itch) in horses in Australia and North America and is discussed elsewhere. Cattle also show considerable irritation during attacks by large numbers of midges. They react with vigorous stamping of the feet, switching of the tail and continuous movement.

The flies are plentiful in the warmer months and are most active at dawn and dusk. Because of their small size they are capable of being carried long distances by wind. Control of the flies is virtually impossible and most measures to reduce their importance are based on preventing access of the flies to the animals. Repellents, especially dimethyl phthalate or o-diethyl toluamide (DEET), are effective on a short-term basis. Antihistamines can be used regularly but are too expensive for general use. Keeping horses away from areas where the flies are present in large numbers is advisable. Backline pour-on treatment of horses with 40 mL of a 4% high CIS permethrin three times weekly gave a good response in 86% of horses. Ivermectin at the recommended dose of 0.2 mg/kg would not produce the serum concentration that would have noticeable effects on blood-feeding *C. variipennis.*

**BLACK FLIES; BUFFALO GNATS; SANDFLIES**

These small gray to black flies (5 mm) are members of the family Simuliidae and include a number of species and genera. The important flies appear to be *Cnephia pecuarum* which is common in the southern states of the United States, *Simulium arcticum* in northern Canada, *Austrosimulium pestilens* and *A. bancrofti* in Australia, and *Simulium ornatum* in Great Britain. These very small flies occur in most parts of the world. With the exception of *S. arcticum* and two or three other species common in northern regions of North America black flies are primarily a concern in tropical regions.

Female flies are voracious blood feeders. They are active in the summer months when large numbers emerge from streams and rivers where they have spent their larval and pupal stages.

*Austrosimulium pestilens* has adapted to reach large numbers, mate, and oviposit within a very short time to utilize the flood situations that occur in northern Australia. The flies congregate in swarms and attack all animals, causing much worry and annoyance. They tend to bite animals around the legs, on the belly and around the head, causing wheals and papules. The annoyance may be so intense that animals stampede or mill about and young animals may be injured or even trampled to death and are frequently separated from their dams. Cattle may spend much of their time wallowing in mud or kicking up dust to keep the flies away. Herding of cattle onto bare areas reduces fly attacks as the flies commonly rest in tall grass, but this reduces feeding. The cause of death is unknown although swelling of the throat causing suffocation, anaphylaxis or direct toxicity are suspected. Filarid worms of *Onchocerca* spp. are transmitted by these flies and their role as an intermediate host of nematodes has been discussed.

A similar situation occurs in northern Canada where large numbers of *Simulium arcticum* have caused severe stress and occasional deaths of cattle introduced into the area of the Athabasca River and similar regions in the province of Saskatchewan. When black fly populations are extreme, previously unexposed cattle develop symptoms of shock resulting from blood loss and cumulative effects of the fly salivary secretions.

Because the larval stages of these flies are passed in flowing streams, large-scale control measures must be directed at killing the larvae at this stage. Aerial distribution of DDT has been effective when added to streams and water supplies or control can be effected by adding insecticides into rivers and canals. However, rapid reinfestation occurs with increased rate of water flow after heavy rains. Annual injection of methoxychlor upstream from major larval sites proved effective in reducing black fly populations, but off-target effects were undesirable. For less ambitious control programs, efforts should be directed towards keeping flies away from animals by the application of repellents or the use of smudge fires. Repellents are of limited use but alcoholic or aqueous solutions and dusts of permethrin, cypermethrin and resmethrin applied to the whole body repelled black flies for some days.

**MOSQUITOES**

A number of mosquitoes including *Psorophora, Aedes, Mansonia, Culex,* and *Anopheles* spp. are important parasites of domestic animals. When the blood feeding females are present in large numbers they cause stress to animals and have been known to kill young pigs and puppies by the severe anemia they produce. Although such occurrences are rarely recorded the blood loss that can occur in severe infestations is surprising. The stress associated with mosquito attack is sufficient to cause reductions in efficiency, even in mature large animals.

Their most important role is as vectors of disease. *Culex tarsalis,* *Aedes dorsalis,* and *A. nigromaculis* transmit equine encephalomyelitis. *Culex tritaeniornynchus* is the principal vector of Japanese B encephalitis in Japan. Various *Culex* species vector Western Equine Encephalitis, Eastern Equine Encephalitis, and West Nile Virus. These viruses can have serious effects on unprotected horses and are transmissible to humans via mosquito bites. Vaccines are available to protect against all of these arboviruses. *Psorophora confinis* is instrumental in spreading the eggs of *Dermatobia hominis,* the tropical warble fly; and *Mansonia* spp. transmit Rift Valley fever. The filarid worm *Setaria digitata* is also spread by mosquitoes.

Control over a large area must include drainage of collections of still surface water or destruction of the larvae by the addition of any one of a number of insecticides, particularly DDT or Abate. For small groups of animals protection from the attacks of mosquitoes can only be satisfactorily effected by mosquito-proof screens. Temporary protection by repellents such as dimethyl phthalate is partial only. Permethrin, 100 mL of a 0.5% emulsion, applied with an electrostatic sprayer provided greater than 70% protection for at least 72 hours.

**HOUSE FLIES (MUSCA DOMESTICA)**

The common house fly has a worldwide distribution and achieves veterinary importance because it is capable of transmitting, in a mechanical manner, the causative bacteria of many infectious diseases. It is often cited as a means whereby anthrax, erysipelas, and brucellosis are spread but its importance in this regard is largely unproven. House flies are intermediate hosts for the larvae of *Habronema muscae* and *Draschia megastoma.*

The eggs are laid in decaying organic matter of any kind. Larval development is temperature dependent and a life cycle may be completed in 12–14 days so that in warm, wet summers the fly population may increase very rapidly, causing annoyance to livestock and farm workers.

House fly population management requires frequent and thorough removal of manure and other rich organic matter. In dry weather the manure can be spread thinly on fields but a more dependable method is to place it in a special fly trap, e.g. Baber's fly traps, from which larvae and adult flies cannot escape. Chemical treatments to control flies require application to resting sites on buildings and other facilities, or the placement of baits containing methomyl, propoxur, naled, or dichlorvos at appropriate locations. Development of insecticide resistance can occur rapidly and there are numerous
examples of resistance to multiple classes of insecticide at a single location. Rotational use of insecticide classes is absolutely essential in the management of resistance.

Management of house fly populations can be augmented through release of parasitic wasps (Family Pteromalidae) that kill pupae. These tiny wasps (1–2 mm long) actively search for the fly pupae and lay one or more eggs inside. The developing wasps devour the fly within the pupa. They have been found useful adjuncts to other fly control measures when used in confined facilities such as hog barns. Intuvulative releases at feedlots, where thousands of wasps are released at regular intervals throughout the fly season, has shown some efficacy but requires an integrated approach with good manure management and selective application of insecticides.

To reduce the fly population in buildings is an important procedure in public health work and many measures are recommended. It is not possible to give details of them here because so many factors have to be taken into consideration, including toxicity of the products used for man and animals, development of resistance to the insecticides, and contamination of food products such as milk by the insecticides.

**BUSH FLIES (MUSCA VETUSTISSIMA)**

These flies occur commonly in Australia, in drier areas, and are a cause of stress to livestock in the summer months. Bush flies die out in southern Australia each winter but breeding continues in the north and the regular northern winds that commence about September each year blow flies southwards and repopulate the areas that are now suitable for breeding. *Musca vetustissima* occur in very large numbers and during the day congregate around the eyes, on the lips, on any visible mucous membrane and on wounds to obtain moisture. They are thought to carry contagious ophthalmia of sheep, infectious keratoconjunctivitis of cattle and contagious eczema of sheep, to delay the healing of wounds, to contribute to the lesions produced by buffalo flies (*Haematobia irritans exigua*) and to act as intermediate hosts for the larvae of *Draschia megastoma, Habronema muscae,* and *Thelazia spp.* Control of the fly population is virtually impossible in the areas where it occurs but individual animals may be protected by repellents such as dimethyl phthalate or o-diethyl toluamide (DEET). Sprays containing 1% of dichlorvos or cyrotophos are effective but must be applied daily. Fenvalerate and cypermethrin give excellent relief and lasting protection against the related *Musca autumnalis.* Dung beetles, introduced from Africa, break up dung pats which will aid in reducing fly numbers.

**FACE FLIES (MUSCA AUTUMINALIS)**

This small fly, indigenous to Europe and Asia, first appeared in North America in 1952 and is now present over large areas of eastern Canada and northeastern and north-central United States. The flies resemble the house fly but are slightly larger. They congregate on the face of cattle, feeding on nasal and lacrimal secretions and saliva. Very large numbers cause a certain amount of stress, cause petechiation in the eye, and are thought to be instrumental in transmitting infectious keratoconjunctivitis (pink eye) of cattle. Face flies are vectors for the eye worms, *Thelazia spp.* which infect the conjunctival sacs and lacrimal ducts of domestic animals. Flies oviposit on fresh cattle manure where larval development takes place. As with all flies development is temperature dependent. In temperate latitudes the flies will over-winter as adults, resting inside homes and other farm structures.

Fly numbers are greatest in summer and cattle are worried particularly when outdoors. Repellents have been extensively used but are not highly successful. Self-applied or hand-applied dusts containing organophosphate insecticides are more extensively used. A dose of 10 mL per animal of 1% cyfluthrin applied as a pour-on reduced fly numbers by 90% and treatment was effective for about 4 weeks. Fenvalerate and cypermethrin give immediate relief, and a lasting reduction in fly numbers when used on fly breeding sites. Reduction of face fly populations on cattle can be achieved through use of synthetic pyrethroids impregnated eartags, but their use is complicated by the presence of insecticide resistant horn flies. Diflubenzuron boluses give 80% control of the immature stages of *M. autumnalis* in the manure for up to 20 weeks.

**HEAD FLIES (HYDROTOEA IRRITANS)**

This small fly, similar in appearance to the house fly but having an olive abdomen and yellow wing bases, is found in the United Kingdom and Europe. It is a non-biting muscid fly that swarms around animals and man from late June to September. Breeding is in soil and litter and there is only one life cycle per year. The lesions on sheep are self-inflicted trauma in attempts to alleviate fly irritation. Sores are often large, open, and may be made more severe by bacterial invasion. The wounds may predispose to blowfly strike by *Lucilia sericata.* The pathogens of summer mastitis of cattle can be spread mechanically by muscid flies, and *Arenobacterium pyogenes* has been shown to persist in *H. irritans* for up to 4 days.

Control is difficult and is similar to that used for the other non-biting muscid fly, *M. autumnalis.* Eartags impregnated with 8.5% cypermethrin or 10% permethrin reduce the severity of fly damage in sheep, and tagged ewes give protection to their lambs. However, it is likely that resistance will quickly occur in the same manner as in the face fly. Pour-on applications of synthetic pyrethroids are easier to apply, are cheaper and leave a higher concentration than a spray or an eartag.

Cyfluthrin 1% applied as a pour-on at a dose rate of 10 mL per animal reduced fly numbers by 90% and gave 4 weeks protection. Crotoxyphos cream is effective but at least two applications are needed. Head-caps are most effective but are tedious to apply.

ITCHMITES (PSORERGATES OVIS, P. BOS)
The 'itchmite' has been recorded as a parasite of sheep in Australia, New Zealand, South Africa, the United States, Argentina, and Chile. Psorergates bos has also been recorded from cattle in the UK. 1

LIFE CYCLE AND EPIDEMIOLOGY
The entire lifecycle of this mite, eggs, larvae, two nymphal stages, and adults, takes place entirely on the host. In sheep the cycle 4–5 weeks. All stages occur in the superficial layers of the skin. The adults are extremely small and can be seen only with the aid of a microscope. Only the adults are mobile on the skin surface and they effect spread of the disease by direct contact. In sheep this often occurs between recently shorn animals when contact is close and prolonged such as when shorn sheep are packed in yards after shearing, or from ewe to lamb while suckling. Mite feeding activity, in addition to excreta causes skin irritation leading to rubbing and biting of the affected parts (principally the sides, flanks, and thighs) and raggedness, sometimes shedding, of the fleece. Wool over these areas becomes thready and tufted and contains dry scales.2

PATHOGENESIS
The skin shows no gross abnormality other than an increase in scurf. Histologically there is hyperkeratosis, desquamation, and increased numbers of mast cells.3 The irritation appears to be a hypersensitivity and results in biting and chewing of the fleece on the flanks and rump behind a line approximately from the elbow to the hips. In the individual sheep and in flocks the disease spreads slowly so that it may be several years before clinical cases are observed and an appreciable number are visibly affected. The incidence of clinical cases in a neglected flock may be as high as 15%. Sheep on poor nutrition have significantly higher mite populations, more scurf and greater fleece derogation.3 Affected sheep may become tolerant after 1–2 years and show no signs, even though they remain infested.

Amongst sheep, Merinos are most commonly affected. The highest incidence is observed in this breed, particularly in areas where the winter is cold and wet. There is a marked seasonal fluctuation in the numbers of mites; the numbers are very low in summer, commence to rise in the autumn, and peak numbers are found in the spring. Spring or summer shearing exacerbates the decline in numbers. Clinically, the disease resembles louse infestation, but may be distinguished on the smaller proportion of the flock affected (10–15%), the less severe irritation and tendency of the sheep to bite those areas it can reach. Hence lesions are confined to parts of the flank and the hindquarters and the wool tufts have a chewed appearance.

CLINICAL FINDINGS
Diagnosis depends on finding the mites in a skin scraping. The selection of sheep with excess scurf and fleece derogation increases the chance of finding mites and in the absence of lice, ked, and grass seed infestation, about 75% of such sheep prove positive for P. ovis. The wool should be clipped as close as possible, the skin smeared lightly with oil and scraped over an area of about 25 cm². The mites have a seasonal incidence and may be very difficult to find in summer and autumn. For best results the scraping should be made on the ribs or shoulder in winter or spring. Scrapings are usually teased out in oil and examined microscopically without digestion. A number of scrapings may be needed from each sheep before mites can be demonstrated. Because of the difficulty of finding mites in summer and autumn, sheep dipped at that time cannot be said to be free of infestation until they prove negative on skin scraping in the following spring, when mite numbers should be at the highest levels.

TREATMENT AND CONTROL
There is no compound available that will eradicate itchmite after a single treatment. Arsenic, lime sulfur, or finely divided sulfur have been used and markedly reduce the number of mites. Because the mites are slow to build up, dipping every second year will mask the signs of infestation. However, arsenic is no longer used in most countries. Finely divided rotenone by itself or mixed with the synergist piperonyl butoxide reduces the mite population. It is usually combined with an organophosphate to include lice and ked control in the one product. Phoxim, an organophosphorus compound, has good activity but two dippings 1 month apart are necessary to eradicate infestations. Amitraz causes a marked reduction in mites that will be maintained for some months.

A single subcutaneous injection of 0.2 mg/kg ivermectin freed sheep of mites up to 56 days post-treatment.4 However these sheep would have to be examined over a longer period to insure eradication. Other macrocyclic lactone products, in various formulations, have been shown to have good efficacy.

DEMODECTIC MANGE (FOLLICULAR MANGE)

Mites of Demodex spp. infest hair follicles of all species of domestic animals. The disease causes little concern but in cattle and goats there may be significant damage to the hide and, rarely, death that may result from gross secondary bacterial invasion.

ETIOLOGY

Mites infesting the different host species are considered to be specific and are designated as Demodex bovis for cattle, D. ovis for sheep, D. caprae for goats, D. equi for horses, and D. phylloides for pigs.

Demodocosis may occur in farm animals of any age, especially those in poor condition but most cases in cattle occur in adult dairy cattle in late winter and early spring. This differs from the well-known condition in the dog which occurs in young, immunodeficient animals.

LIFE CYCLE AND EPIDEMIOLOGY

The entire life cycle is spent on the host. Adult mites invade the hair follicles and sebaceous glands which become distended with mites and inflammatory material. The life cycle consists of the egg, larval, and two nymphal stages. The disease spreads slowly and transfer of mites is thought to take place by contact, probably early in life. Calves can acquire mites from an infected dam in half a day. However in horses grooming instruments and rugs may transmit infection.

PATHOGENESIS

Invasion of hair follicles and sebaceous glands leads to chronic inflammation, loss of the hair fiber and in many instances the development of secondary staphylococcal pustules or small abscesses. It is these foci of infection which cause the small pinholes in the hide which interfere with its industrial processing as well as reducing the value dramatically. In most farm animals the lesions are difficult to see externally and only the advanced ones will be diagnosed.

CLINICAL FINDINGS

The important sign is the appearance of small (3 mm diameter) nodules and pustules which may develop into larger abscesses, especially in pigs and goats. The small lesions can be seen quite readily with a strong light source. However, lesions in hides can be detected as dark spots when a fresh hide is viewed when a fresh hide is viewed. Lesions in hides can be detected, but usually there is no pruritus and hair loss is insufficient to attract attention. The contents of the pustules are usually white in color and cheesy in consistency. In large abscesses the pus is more fluid. In cattle and goats the lesions occur most commonly on the brisket, lower neck, forearm, and shoulder, but also occurs on the dorsal half of the body, particularly behind the withers. Larger lesions are easily visible but very small lesions may only be detected by rolling a fold of skin through the fingers. In horses the face and around the eyes are predilection areas. Demodocosis in pigs usually commences on the face and spreads down the ventral surface of the neck and chest to the belly. There is little irritation and the disease is observed mainly when the skin is scraped at slaughter. The disease may be especially severe in goats, spreading extensively before it is suspected and in some instances causing deaths. Severe cases in goats commonly involve several skin diseases such as mycotic dermatitis, ringworm, besnoitiosis and myiasis. Demodocosis is rare in sheep. In this species pustules and scabs appear on the coronets, nose, tips of the ears, and around the eyes, but clinical signs are not usually seen and mites may be found in scrapings from areas of the body not showing lesions.

CLINICAL PATHOLOGY

The characteristically elongated mites are usually easy to find in large numbers in the waxy material which can be expressed from the pustular lesions. They are much more difficult to isolate from squamous lesions. Lesions in hides can be detected as dark spots when a fresh hide is viewed against a strong light source. However, lesions may not be readily seen until the hair has been removed and the skin has been soaking for some time.

DIFFERENTIAL DIAGNOSIS

- The commonest error is to diagnose the disease as a non-specific staphylococcal infection
- In cattle and goats the disease often passes unnoticed unless the nodules are palpated
- Deep-seated ringworm in horses has much in common with demodocosis
- A satisfactory diagnosis can only be made by demonstration of the mite.

TREATMENT AND CONTROL

Repeated dipping or spraying with the acaricides recommended for other mange is usually carried out but is more to prevent spread than cure existing lesions. Ivermectin which does not eradicate the infection in dogs, possibly because of the difficulty in getting the acaricide to the mite, has been reported to cure 98% of beef bulls when used at 0.3 mg/kg. Ivermectin in a premix, fed for 7 consecutive days has been reported to clear the infestation in pigs.

REFERENCES

SARCOPTIC MANGE (BARN ITCH)

Sarcoptic mange occurs in a wide variety of host species causing a severe pruritic dermatitis. While in most countries it has been a major problem and was a reportable disease, the advent of macrocyclic lactone endectocides has reduced the incidence of disease dramatically.

ETIOLOGY

The causative mite, Sarcoptes scabiei, is usually considered to have a number of varieties each generally specific to a particular host species. Morphological, immunological and molecular research confirms the close relationship among the varieties, but do not explain the biological differences, particularly with respect to host specificity. Because host specificity is not strict and transference from one host species to another can occur there is some concern when attempting to control the disease.

Animals in poor condition appear to be most susceptible, but conditions, especially overcrowding, in which sarcoptic mange occurs often go hand in hand with poor feeding and general poor husbandry. The disease is most active in cold, wet weather and spreads slowly during the summer months.

LIFE CYCLE AND EPIDEMIOLOGY

Female mites form shallow burrows in the lower stratum corneum of the skin in which they deposit eggs. Development for both sexes includes a larval stage, two nymphal stages prior to molting to the adult. All life cycle stages, except the eggs, can be found on the skin surface and are thus easily transferred to other hosts. The normal exfoliation of the skin eventually exposes the tunnels exposing eggs as well. The life cycle from egg to egg takes 10–13 days.

Although direct contact between hosts is the most effective method of transmission inert materials such as bedding, blankets, grooming tools, and clothing may act as carriers. Adult mites do not usually survive for more than a few days away from the host but in optimum laboratory conditions they may remain alive for up to 3 weeks. In pigs adult sows are often the source of infestation for young pigs even though they show no signs of the disease. Large numbers of mites can often be found in the ears of normal sows and the mites are transmitted soon after farrowing. Significant scratching does not occur until a hypersensitivity develops some 8–10 weeks later and may continue until slaughter.
A small proportion of young pigs do not develop a hypersensitivity and these become chronically affected. Amongst domestic species pigs are most commonly affected, but it is an important disease in cattle and camels and occurs in sheep. It has been a notifiable disease in most countries, because of its severity, but a decline in prevalence accompanying the advent of new therapeutics has resulted in the removal of this requirement in some countries. People handling infested animals may become infected but lesions will disappear if further contact is prevented.

Infested animals develop protective immunity and are able to clear challenge infestations rapidly. A proportion of infested hosts do however remain chronically infested and mite populations may show a post-parum recrudescence thereby facilitating transfer to the susceptible offspring.

PATHOGENESIS
Young animals, in particular piglets, become infected in the first few weeks of life and develop a hypersensitivity within 8-10 weeks. This allergic phase lasts for 8-9 months and during this time affected animals are constantly itchy. The disease, if untreated, progresses to a localized crust formation characteristic of a chronic hyperkeratotic state.

Many infestations in pigs have little or no effect on weight gain although there is some controversy and treatments improve productivity. In some pigs the loss of condition, production and vitality may be severe, and the appearance of affected animals is esthetically displeasing. Erythema, papules and intense pruritis may be seen. Few mites may be necessary to cause a reaction in a previously sensitized animal. A chronic condition is uncommon but is seen in pigs with an immunodeficiency.

In cattle and camels, severe hypersensitivity lesions occur and often lead to death. Sheep initially show an intense pruritis and rub the affected part against fences or bite at the skin. Later papules and vesicles occur and the skin becomes thickened, covered with pale scabs and the hair is lost.

CLINICAL FINDINGS
Early lesions are characterized by the presence of small red papules and general erythema of the skin. The affected area is intensely itchy and frequently exoriated by scratching and biting. Loss of hair, thick brown scabs overlying a raw surface, and thickening and wrinkling of surrounding skin soon follow. In pigs the lesions commence on the trunk, in sheep and goats on the face, in cattle on the inner surface of the thighs, the underside of the neck and brisket and around the root of the tail, and in horses and camels on the head and neck. Except in sheep where the lesions do not spread to the woolled skin, lesions become widespread if neglected and such animals may show systemic effects including emaciation, anorexia, and weakness, and in neglected cases death may occur.

The course of sarcoptic mange is rather more acute than in the other forms of mange and may involve the entire body surface of cattle in a period as short as 6 weeks.

CLINICAL PATHOLOGY
Necropsy examinations are not usually undertaken. Deep scrapings which draw blood are required for accurate diagnosis and must be taken from the edges of any evident lesions. Examination of scrapings either directly or after digestion in 10% potassium hydroxide will reveal mites and/or eggs. When practical multiple scrapings from affected animals should be taken. Examination of the ear wax of pigs often shows mites when none can be seen in scrapings.

Change in behavior, a result of the intense pruritis, have been used in swine as an initial diagnostic tool. An increase in the rubbing index is indicative of infestation, but other clinical confirmation is required.

An ELISA for detection of antibodies to *Sarcoptes scabiei* has been developed. The test has high specificity and moderate sensitivity, being more sensitive in young animals undergoing their first infestation. It has been shown to work well in herd level eradication programs and functions afterward as an effective surveillance tool.

DIFFERENTIAL DIAGNOSIS

- Sarcoptic mange is the only mange which occurs in pigs. It can be confused with infestation with *Tyrophagus spp.* mites or lice, or with swineepox, parakeratosis, infectious dermatitis, psoriasiform rosea, and ringworm. In most of these diseases there are clinical features which are characteristic and final diagnosis can be made on the presence or absence of the mite
- The same comments apply to the differentiation in cattle of sarcoptic mange from chorioptic and psoroptic mange and from chloromethyl naphthalene poisoning and ringworm
- Horses may be affected by psoroptic or chorioptic mange but the lesions are most common at the base of the mane and tail and at the back of the pastern respectively
- Infestation with the trombidiform mites and photosensitisation may resemble sarcoptic mange
- The disease is uncommon in sheep.

TREATMENT AND CONTROL
Macroyclic lactone endectocides (including ivermectin, eprinomectin, moxidectin, and doramectin) are the preferred products for treatment of sarcoptic mange. Use of these products in pour-on or injectable formulations are highly efficacious when used at the label recommended dose. Because of the residual activity of these compounds retreatment is not usually necessary although moxidectin given subcutaneously at 0.2 mg/kg to infected sheep resulted in a rapid clinical improvement but did not eliminate the mites. Two doses 10 days apart resulted in negative skin scrapings by 14 days post-treatment. A single injection to cattle eliminated the mites by day 14. The resolution of the lesions may take considerable time, but should not be misconstrued as product failure.

Prefarrowing treatment with ivermectin to prevent transmission to the newborn piglets improves weight gains and early feed conversion.

If other treatments are used they must be thoroughly applied so that all parts of the skin, especially under the tail, in the ears and between the legs are wetted by the acaricide. Although buildings, bedding, and other inert materials do not support the mite for more than a few days they should also be treated unless they can be left in a dry state for 3 weeks.

Treatments should be repeated three times at 7-day intervals. For sows this should commence 3 weeks before farrowing. Special attention should be paid to the ears. Tichlorfon, malathion (0.5%), diazinon (0.02%), coumaphos (0.05–0.1%), fenchlorphos, chlordrinphos, amitraz (0.1%), and phoxim (0.025%) have been used. All animals should be treated. Phosmet 20% applied as a pour-on at weaning eliminated *Sarcoptes* and allowed 12% increase in live weight gain.

REFERENCES
Psoroptic mange (Sheep Scab, Body Mange, Ear Mange)

Psoroptic mange is of greatest importance in sheep, in which it causes sheep scab, but it is also responsible for body mange in cattle and horses and ear mange in horses, sheep, goats, and rabbits. The disease is a major animal welfare concern.1

Etiology

The various species of Psoroptes have now been reduced to two or three species.2 Based on molecular evidence3 P. ovis, P. cuniculi, and P. cerminus are identical despite differences in morphology and biology. It is clear that P. ovis from cattle and sheep are identical although cross-transmission is not always successful.4 P. equi occurs on horses, donkeys, and mules in Great Britain and P. natalensis on cattle and the water buffalo. The ear mites are all P. cuniculi and recent work has suggested this is a variant of P. ovis adapted to the aural environment. P. cerminus assumes a dual role, being an ear mite of the American bighorn and a body mite of the wapiti.

Life Cycle and Epidemiology

Psoroptic mange is a major disease in sheep which was once virtually eliminated in most progressive countries where wool production is an important industry. With the cessation of organophosphate dips in the UK there has been a resurgence of the problem. The disease in cattle was widespread in the United States but has now largely been brought under control. It can spread rapidly and cause serious losses in cattle if neglected as shown by the serious losses that can occur in feedlots.

The ear manges cause irritation and, in horses, a touchiness around the head. Psoroptic mites abrade the surface and feed on lipid exudate, bacteria, and skin debris.5 Erythrocytes are not normally a constituent of the diet and may be accidentally ingested when host scratching results in skin breakage.6 They cause the formation of scabs, under which they live. The eggs are laid on the skin at the edge of a scab and hatch in 1–3 days, although some may occur. However, it is possible to have the disease in a flock at a very low level of incidence and with minimal lesions. This usually occurs when the sheep are highly resistant because of good nutrition, or climatic conditions are adverse for mite development, or treatment has been carried out but has been incomplete. In such cases there may be little or no clinical evidence of the disease and a careful search for latent cases may be necessary. This is facilitated by packing the animals into a confined space, so that the mites become active, and watching for signs of itchiness.

Behavioral changes in infested sheep are dramatic with sheep biting at the affected areas, rubbing or scratching. In addition infested sheep exhibited stereotypic behaviors typical of animals under stress.7 These changes combine to reduce productivity. Animals exhibiting these changes should be carefully examined by palpating the surface of the skin in search of papules and scabs. Special attention should be paid to the ears, the base of the horns, the infraorbital fossa and the perineal and scrotal areas in rams.

Goats

Lesions can vary from a dry crusty scab on the external ear canal with no clinical signs to severe lesions covering much of the body and causing death. However, it is commonly an ear mite, feeding on whole blood, and causing the production of scabs which vary from a single layer lining the large sulcus at the base of the concha to abundant laminated scab formation occluding the meatus. In severe cases the poll may be affected, and scabs may also be found on the pasterns. Female goats serve as the source of infection for the kid; mites may be found by palpation of the base of the horns, the infraorbital fossa, the perineal and scrotal areas in rams.

Horses

Ps. equi causes the production of large, thick crusts on those parts of the body carrying long hair, the base of the mane and the root of the tail, and hairless areas such as the udder, prepuce, and axillar. Affected parts are itchy, the hair is lost and with constant rubbing the surrounding skin becomes thickened. P. cuniculi infestations in horses cause severe irritation in the ear accompanied by discharge, shaking of the head, rubbing of the head, and tenderness of the poll.

Cattle

Typical lesions appear first on the withers, neck, and around the root of the tail. In severe cases they may spread to the rest of the body. The lesions are intensely itchy. They commence as papules but soon are covered with a scab which enlarges peripherally and coalesces with other
lesions so that very large areas of skin may become involved. The hair is lost, the skin becomes thickened, wrinkled, and covered with scabs. Badly affected animals becomes weak and emaciated, and may die.

**CLINICAL PATHOLOGY**

The mites can be easily demonstrated in scrapings taken from the edges of the lesions. Examination is facilitated by prior digestion of the scraping in warm, 10% potassium hydroxide solution.

An ELISA has been developed for diagnosis of *Psoroptes* infestation in sheep. It has been applied to monitoring of infestations as part of efficient control programs.

**DIFFERENTIAL DIAGNOSIS**

- Severe cases of psoroptic mange in sheep are similar to myotic dermatitis except that there is no itching in the latter. Disease causing itchiness such as scrape, ked, and louse infestations and infestations with *Psorergates* ovis and harvest mites do not have typical cutaneous lesions and the latter group can usually be detected by examination for the causative parasites.
- In horses attention is drawn to the condition because of the horse rubbing its head, by swelling around the base of the ear, or by resenment to the bridle passing over the ears. In some horses the affected ear may droop.

**TREATMENT AND CONTROL**

Macrocyclic lactone endectocides are used most frequently for control of *psoroptid* scabies. Cattle treated with ivermectin must be separated from non-infested cattle for 2 weeks, otherwise spread and re-infection may occur. In sheep two treatments of ivermectin 0.2 mg/kg subcutaneously are necessary to eliminate infestations.

Moxidectin applied as a 0.5% pour-on at 0.5 mg/kg to cattle is effective against *P. ovis* as well as lice and *Chorioptes botris* and was equally effective against *P. ovis* at 0.2 mg/kg by subcutaneous injection.

In sheep, although a single subcutaneous dose of 0.2 mg/kg moxidectin gave a rapid clinical improvement, two doses 7 days apart were necessary to eliminate mites.

In large scale field use, sheep receiving a single injection in the autumn remained free of the infestation throughout the winter, while two injections 10 days apart were effective in treating outbreaks.

Doramectin injectable at 200 µg/kg was highly effective in eliminating mites in scrapings of infested cattle. The same treatment was found to protect cattle from infestation for up to 3 weeks.

If sheep are to be dipped, it is important to wet the skin thoroughly and pay special attention to severe cases where mites are likely to be present in inaccessible sites on the body. Thus a plunge dip is almost essential and the sheep must be kept immersed in the dipping fluid for at least one minute. Prior shearing may be advisable but may lead to further spread of the infestation. Care must be taken to insure that the concentration of the acaricide in the dip is maintained, especially when large numbers of sheep are being treated. Badly affected animals should be kept side and inaccessible sites including ears, horn bases, and perineum treated manually with the dipping fluid. Dipped sheep should not be returned to their pastures, nor to the barn unless the latter has been thoroughly cleaned and sprayed with the dipping fluid.

Diazinon (0.01%), propetamphos (0.125%), and flumethrin (0.055%) will all eliminate *P. ovis* from sheep with a single dipping and will give at least 4 weeks of protection. Coumaphos (0.1%), phoxin (0.05%), and amidrin (0.05%) require two treatments at 7–10 day intervals to eliminate infestations. The synthetic pyrethroids are variable in their efficacy. Fumethrin, used as a non-stripping dipping compound, eradicated *P. ovis* from sheep when used at 55 ppm and gave at least 7 weeks of protection. Fenvalerate (0.05%) used twice will also clear infected cattle, but another synthetic pyrethroid, cypermethrin, when used at 150 ppm did not eliminate infestations after three treatments.

In horses affected ears should be cleaned of all wax and ear preparations containing benzene hexachloride should be used at weekly intervals. Local treatment of diazinon or propetamphos could also be used. Benzyl benzoate is a safe and effective treatment when given every 5 days for three treatments. Ivermectin is highly effective against *P. equi*.

Eradication of sheep scab on an area basis is usually undertaken by quarantine and compulsory treatment of all susceptible animals in the area at the same time. Now that there are effective treatments that do not require dipping, eradication of scab from areas should be more easily accomplished. The necessity to dip all animals in the area during a short period presents difficulties and the cost of construction of dips and lack of desire to dip in cold climates are other obstructing factors. The use of pour-ons or injections is an alternative attractive to providing helminth control in late season lambs and in ewes. Further, even pregnant animals can be yarded and treated by subcutaneous injection or pour-on as long as care is taken in the yards. Where it is desired to keep the disease at a low level of eradication, the disease is made notifiable, movement of stock is restricted and infested farms are quarantined.

**REFERENCES**

**CHORIOMICANE MANGE (TAIL MANGE, LEG MANGE, SCROTAL MANGE)**

Chorimicon mange is the commonest form of mange in cattle and horses. While the primary effect on cattle is esthetic damage there are production effects in dairy animals. In horses leg mange is a source of annoyance and inefficiency at work. In sheep it affects the scrotum and may cause a decrease in fertility.

**ETIOLOGY**

Chorimicon mites were formerly named according to the host species but those on cattle, horses, goats, and sheep are now considered to be one species, *Chorioptes bovis*. Another species, *C. texanus*, has been reported on goats, cattle, and Canadian reindeer. In cattle, the mites are much more active in the latter part of the winter and tend to disappear in cattle at pasture. This diminution in activity is not noted in cattle kept housed in the summer.

**LIFE CYCLE AND EPIDEMIOLOGY**

*Chorioptes bovis* feed on the skin surface, abrading the upper layers with their mouthparts and contaminating the area with salivary secretions and excreta. Developmental stages are similar to that of *Psoroptes* and a complete cycle, from egg to adult, requires approximately 3 weeks. The number of parasites is influenced by temperature and humidity; the mite populations beginning to increase on sheep in early autumn, numbers reach a peak in late autumn or early winter and decline in spring. In cattle the cycle is longer, peak numbers occurring in late winter and early spring and declining in summer.
Transmission is probably effected by direct contact in most instances although in animals housed in barns, grooming tools may be an additional method of spreading the disease. Infestation of bedding is not a common method of transmission.

In horses, the parasites occur almost entirely in the long hair on the lower parts of the legs and are rarely found on other parts of the body. In cattle the disease is most evident in the winter, lesions occurring most commonly on the perineum, and back of the udder, extending in severe cases to the backs of the legs and over the rump. In the summer months the mites persist entirely in the long hair on the lower parts of the hindlegs and thighs. Sheep are more heavily infected than ewes and probably infect ewes while copulating. Lactating ewes probably act as the source of infection for lambs.

**PATHOGENESIS**

The mites cause an allergic, exudative dermatitis; the yellowish serous exudate coagulates and breaks so that small scabby lesions are seen on the hair. In horses the mites cause severe irritation and itchiness. The initial lesion in cattle is a small nodule which exudes serum causing matting of the hair. In severe cases these coalesce to form heavy scabs and cause thickening and wrinkling of the skin. Mites can be isolated from many animals which show no clinical evidence of the disease. While most cases do not cause any symptoms, a rapidly spreading syndrome characterized by coronitis, intense irritation and a marked fall in milk production has been reported. *C. bovis* is a common parasite of sheep in the United States, New Zealand, and Australia, and causes an allergic exudative dermatitis on the scrotum of rams. This may cause a rise in temperature of the scrotal contents and a severe testicular degeneration if the lesion has an area greater than 10 cm².[1]

**CLINICAL FINDINGS**

The first sign in horses is usually violent stomping of the feet and rubbing of the back of the hind pasterns on wire, rails, or stumps. This is most evident during periods of rest and at night. Examination of the area is difficult because of the long hair present and the horses may resist manipulation. In cases of long duration the skin is seen to be swollen, scabby, cracked, and usually greasy; small amounts of serous exudate may be attached to most hair in the affected area.

Cattle show little evidence of cutaneous irritation but the small crusty scabs (3 mm diameter) on the escutcheon, udder, and thighs are unsightly. Although the mites appear to cause little trouble in the summer, occasional animals are seen which have thick, crusty scabs on the skin, just above the coronets and around the muzzle.

The main lesion in sheep is seen on the scrotum of rams where an allergic dermatitis results in the production of a yellowish serous exudate over areas from a few millimeters to several centimeters.[1]

**CLINICAL PATHOLOGY**

Scrapings from the affected areas usually contain large numbers of mites.

**DIFFERENTIAL DIAGNOSIS**

- Greasy heel in horses resembles chorioptic mange except that pain is more evident in the former and itchiness in the latter. It has been suggested that the two diseases are etiologically related
- The lesions in cattle may go unnoticed but are not likely to be mistaken for those of any other disease with the possible exception of other manges. The presence of chorioptic mites in footrot and mucosal disease lesions may be purely coincidental, but cases of chorioptic mange which have lesions around the coronet and muzzle may be mistaken for one of the erosive diseases
- Sheep with itchy, scabby legs may be infested with other forms of mange or have contagious eczema or strawberry footrot.

**TREATMENT AND CONTROL**

The macrocyclic lactone endectocides have shown efficacy against *Chorioptes* spp., but eradication of the parasites from a herd is difficult. Moxidectin 0.5 mg/kg applied as a pour-on eliminated *C. bovis* as well as sucking lice and *Psoroptes ovis.*[3] When given as a single injection of 0.2 mg/kg there was a marked decline in the number of mites but few cattle were cleared of infection.[4] Doramectin has high efficacy at the label rate in cattle, but a single treatment did not clear mites from all of the trial animals.[5] Treatment with ivermectin at recommended rates was completely effective, but mites persisted for at least 14 days.[7]

Two doses of 2 mg/kg flumethrin applied to the whole body 1 week apart eliminates mites from cattle, while treatment of 2 mg/kg was successful if applied to the caudal region.[6] Fenvalerate 0.05% also killed all mites while amitraz 0.05% removed 98%.[7] Phoxim 0.05% and 0.1% used twice at 10-day intervals has also eradicated the infection from cattle.[8] Other compounds if used repeatedly will reduce mite numbers but recrudescences may occur. Ivermectin 0.2 mg/kg given subcutaneously on two occasions reduced but did not eliminate the infestation on cattle. A single treatment of infested horses with ivermectin paste did not remove all mites but when combined with hair removal, washing encrusted areas with oil of salicylic acid and the later removal of crusts with a stiff brush, eradication was achieved.[9]

**Introduction**

Among domestic farm animals, the metabolic diseases achieve their greatest importance in dairy cows and pregnant ewes. In the other species, these diseases occur only sporadically. The high-producing dairy cow always verges on abnormal homeostasis and the breeding and feeding of dairy cattle for high milk yields is etiologically related to metabolic disease so common in these animals.

The salient features of the common metabolic diseases of farm animals are summarized in Table 29.1.

**Periparturient period in cattle and sheep**

As milk production in dairy cows increases and as herds become larger, the incidence of metabolic disease increases. In dairy cows, the incidence of metabolic diseases is highest in the period commencing at calving and extending until the peak of lactation is reached and their susceptibility appears to be related to the extremely high turnover of fluids, salts and soluble organic materials during the early part of lactation. With this rapid rate of exchange of water, sodium, calcium, magnesium, chlorides and phosphates, a sudden variation in their excretion or secretion in the milk or by other routes, or a sudden variation in their intake because of changes in ingestion, digestion or absorption, may cause abrupt, damaging changes in the internal environment of the animal. It is the volume of the changes in intake and secretion and the rapidity with which they can occur that affects the metabolic stability of the cow. In addition, if the continued nutritional demands of pregnancy are exacerbated by an inadequate diet in the dry period, the incidence of metabolic disease will increase. The effect of pregnancy is particularly important in ewes, especially those carrying more than one lamb.

**Transition period in dairy cows**

The literature on managing the transition period of the cow from 3 weeks before parturition to 3 weeks after parturition to optimize health and productivity has been reviewed. It is a crucial stage in the production cycle of the dairy cow; no other period can affect subsequent production, health, and reproductive performance so greatly. The success of the transition period effectively determines the profitability of the cow during that lactation. Nutritional or management limitations during this time may impede the ability of the cow to reach maximal milk production. The primary challenge faced by cows is a sudden and marked increase of nutrient intake as parturition approaches may be followed by a description of a fat mobilization syndrome in early lactation, in which cows mobilized body lipids from adipose tissue and deposited lipids in the liver, muscle, and other tissues. This was followed by descriptions of elevated non-esterified fatty acid concentrations during the last 7 days before calving being associated with a greater incidence of ketosis, displaced abomasum and retained fetal membranes but not of milk fever. Understanding the metabolism of NEFA by the liver is a critical component of understanding the biology of the transition cow. Extreme rates of lipid mobilization lead to increased uptake of NEFA by the liver and increases triglyceride accumulation. If this lipid infiltration becomes severe, the syndrome of hepatic lipidosis or fatty liver may result, which can result in a prolonged recovery from other diseases, increased incidence of other diseases, and increased susceptibility to induction of ketosis.

It is now known that lipid metabolism in the prepartum dairy cow is important in the occurrence of displaced abomasum. Significant risk factors for displaced abomasum included a negative energy balance prepartum (as estimated from plasma NEFAs), a high body condition score, suboptimal feed bunk management.
Metabolic tests can now be used to predict displaced abomasum in dairy cattle. In cows which develop a left-side displacement of the abomasum, mean BHBA concentrations \( \geq 1200 \mu mol/L \) were 8 times greater in cows with subsequent LDA. The odds of LDA were eight times greater in cows with BHBA concentrations \( \geq 1200 \mu mol/L \) who were 3.4 times more likely to develop LDA. Serum calcium concentrations were not associated with LDA. In summary, strategic use of metabolic tests to monitor transition dairy cows should focus on NEFA and BHBA in the last week prepartum and BHBA in the first week post partum.

The nutritional management strategies to optimize the metabolic health of transition cows has been reviewed. During the transition period, dairy cows undergo large metabolic adaptations in glucose, fatty acid, and mineral metabolism. The practical goal of nutritional management during this period is to support these metabolic adaptations. A 2-group nutritional strategy for dry cows to minimize overfeeding of nutrients during the early dry period but increase nutrient supply during the late dry period is now being recommended. Increasing the amount of energy supplied through dietary carbohydrate during the prepartum period results in generally positive effects on metabolism and performance of transition cows. But the form of that carbohydrate (whether starch or highly digestible neutral detergent fiber) may be of lesser importance. Attempts to increase energy supply by feeding dietary fat sources or decrease energy expenditure by supplying specific fatty acids such as trans-10, cis-12 conjugated linoleic acid to decrease milk fat output during early lactation do not decrease the release of nonesterified fatty acids (NEFA) from adipose tissue.

In addition to nutritional management strategies to optimize health of the transition cow, certain feed additives are in use to reduce subclinical ketosis and reduce the incidence of displaced abomasum. Monensin is a carboxylic polyether ionophore produced by a

</tbody>
</table>
naturally occurring strain of *Streptomyces cinnamomensi*. Monensin exerts its many effects by shifting the microbial populations in the rumen. It changes the ratio of volatile fatty acids in the rumen, increasing propionic acid and reducing the molar percentages of butyric acid and acetic acid. Improved rumen propionic acid improves gluconeogenesis. When administered in controlled release capsule (CRC) 2-4 weeks before calving, monensin reduced the incidence of both clinical ketosis and displaced abomasum post-calving. In a large dataset, monensin showed a trend for a 25% reduction in the incidence of retained placenta. Monensin improves energy metabolism which reduces the incidence of all three 'energy associated diseases', retained placenta, displaced abomasum and clinical ketosis. In Canada, the monensin-controlled release capsule (CRC) is approved as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The capsule delivers 335 mg of monensin daily for 95 days. Cows treated with the monensin CRC 3 weeks before calving had decreased NEFA and BHBA and increased concentrations of serum cholesterol and urea in the week immediately pre-calving. Monensin has no effect on calcium, phosphorus, or glucose in the pre-calving period. After calving, concentrations of phosphorus were lower and BHBA lower and cholesterol and urea higher in monensin-treated cows. The lower NEFA values indicate less fat mobilization and the higher cholesterol suggest greater lipoprotein export from the liver. The higher urea levels are thought to be due to a protein-sparing effect in the rumen, resulting in an increased supply of amino acids in the small intestine. There was no effect of treatment on NEFA, glucose, or calcium in the first week post-calving. Monensin treatment administered pre-calving significantly improved indicators of energy balance in both the immediate pre-calving and post-calving periods.

Abnormalities of the blood levels of the four macrominerals, calcium, phosphorus, magnesium, and potassium in the cow during the transition period are involved in subclinical hypocalcemia, clinical milk fever, hypomagnesemia, and acute hypokalemia.

Knowledge of the complex behavioral needs of the dairy cow is essential in order to provide adequate housing during the transition period. In North American dairy herds, the flow of cows through the transition period often necessitates many changes of pens, which are disruptive to the social organization of cow groups. Stocking rates that exceed stall and feed bunk capacity place even greater challenges on the dairy cow at this time. Alternative strategies for cow grouping and improvements in pen and stall design which provide greater behavioral freedom for the dairy cow and improvements in health and productivity have been described.

Management of the dairy cow at calving time is a major topic which requires that the veterinarian educate the animal attendants and owners. The objective is to ensure the delivery of a viable, live calf and smooth transition of the cow without complications, from the dry period to the lactation period. The two major problems encountered at calving time are dystocia and perinatal mortality.

The diagnosis and treatment of dairy cows with periparturient diseases requires a program suited to the particular herd. Particularly in large herds, there is a need for collaboration between the veterinarian, nutritionist, manager of the herd, and the animal attendants. Specific procedures should be developed for each herd based on past experience with the problems of recently-calved cows, the facilities, the skills of the workers, the priorities of management, and the flow patterns of cows in the herd. Every effort must be made to prevent periparturient diseases in the cows. In general, diseases in the early post partum period originate in the feeding and management of the dry cow. Important principles include a protocol of grouping parturient cows according to the feeding program and handling facilities on the farm. Groups of cows can be screened for mastitis, visual evidence of illness, daily milk yield, body temperature, urine pH, palpated for evidence of metritis. Individual cows which have been identified by a screening method must be examined individually to make a diagnosis and decide on a treatment protocol based on the particular diagnosis.

The use of reliable records to monitor the health and production of dairy cows during the transition period is essential to evaluate the efficacy of programs at the farm level. Monitors of transition cow management programs will assist in determining how well cows are prepared for milk production and good health in the coming lactation. Appropriate monitoring will focus on three areas: cows that die or are culled in early lactation, the productivity of the surviving cows in early lactation, and the rates of disease in the periparturient period.

Cows which leave the herd in the first 60 days of lactation are usually culled because of disease or injury. Removal rates and their causes can be a critical monitor of the efficacy of transition cow management programs. Measuring productivity and health of cows in early lactation involves monitoring peak milk, daily milk yields, first test mature equivalent 305-day projected milk, milk components at first Dairy Herd Improvement Association (DHIA) test day, milk fat percentage, ratios of test-day components, somatic cell count at first DHIA test day. DHIA records also allow comparison of the performance of each cow in early lactation to her performance in the prior lactation. Comparisons can be made of the changes in somatic cell count between the last test of the prior lactation and the first test of the current lactation and mature equivalent 305-day difference from the prior lactation to the first test of the current lactation.

Health and production records in dairy herds have traditionally emphasized reproductive events and treatments given. The records should capture the information about the common diseases which occur in most dairy herds. The record system should be set up to:

- Monitor rates of well-defined disease events as a measure of the effectiveness of health and production programs and to aid problem solving
- Determine the clinical efficacy of treatments by monitoring retreatment rates for specific diseases
- Maintain an individual cow history record for cow-side use to enhance treatment decisions
- Measure compliance and consistency of implementation of the health program being used
- Reconcile pharmaceutical purchases with treatment protocol entries and to meet regulatory requirements on the use of pharmaceuticals in food animals
- Determine the costs of certain disease rates over achievable targets. The costs of specific diseases are compelling to most dairy herd producers. Good records can generate an incidence rate of common diseases. These costs include the immediate cost of treatment, the cost of the veterinarian's and herdsmen's time and the cost of milk withheld from the market. For the majority of diseases of recently-calved cows, the cost per disease in the USA is about US$320.00 with a range from $150 to $450 as from the year 2001.

An adequate record system will allow producers and veterinarians to determine the differences between actual performance and benchmark performance and then determine the causes of the shortfall. The most important determinants of profitability on dairy farms are milk income and feed cost and the difference between milk income and feed costs is the return over feed index (ROF). Many factors affect the ROF index. These include: three times daily milking, component percentages in the herd milk test, milk fat and protein percentages, use of an E. coli mastitis vaccine
and use of monensin in the lactating cow diet. One of the most important factors associated with profitability is milk production. From 80% to 95% of the income on dairy farms is derived from milk sales. Thus, it is critical that the producer, the veterinarian and other advisors collaborate to plan the animal health and production program which will result in the optimum ROI.

Other recent developments indicate that environmental and management factors can be manipulated to ease the transition into lactation. The photoperiod, defined as the duration of light exposure an animal receives within a day, can be adjusted to produce dramatic effects on periparturient health and subsequent lactational efficiency. Increasing the frequency of milking in the immediate post partum period also produces persistent increases in milk yield and improvements in mammary health. In both techniques, evidence is emerging to support the concept that alteration of prolactin sensitivity is the mechanism underlying health and production responses.

The prospect of 0 days for dry periods are being explored as a possible alternative management scheme in dairy herds. In high-producing dairy cows, the dry period is influenced by parity and management practice. Multiparous cows that were continuously milked and treated with bovine somatotrophin (bST) demonstrated negligible production losses in the next lactation. First-calf heifers, however, demonstrated large reductions in milk yield.

**Voluntary dry matter intake in periparturient dairy cattle**

The factors affecting voluntary dry matter intake (VDMI) of lactating cattle are extremely important and have received much attention for many decades. The literature on the integration of metabolism and intake regulation in animals has been reviewed. A substantial dip in VDMI is initiated in late pregnancy and continues into early lactation. Pregnancy in dairy heifers has been shown to reduce VDMI from week 26 of pregnancy by 1.53% (approximately 0.17 kg) per week until 3 weeks before calving. In one study, in which the energy density of the diet remained constant during the last 168 days of pregnancy, a similar decline in energy intake during the last trimester of pregnancy both in heifers and lactating cows when diet energy was high (11.6 M) of metabolizable energy/kg of DM), while the decline was much smaller or insignificant at lower energy densities (10.3 or 8.3 M) of metabolizable energy/kg of DM). The lowest VDMI occurs at calving. Post partum VDMI increases, but the rate varies widely. In cows given diets of constant composition, the milk yield typically peaks at 5–7 weeks post partum, while the maximum intake is reached between 8 and 22 weeks after calving. The increase in intake from week 1 post partum to time of peak intake varies from between 2% and 111%. These differences in intake are affected by the diet fed during lactation but may also depend on prepartum feeding by way of, at least in part, the influence and the degree of fatness and or body condition score (BCS) of the animal. Voluntary dry matter intake is considerably higher in multiparous cows compared with primiparous cows. The intake capacity of primiparous cows calving at an age of 2 years is only about 80% of that of multiparous cows in the first part of lactation. The normal pattern of intake may be severely influenced by disease states. Both clinical and subclinical infections are known to substantially reduce appetite and performance.

The dip in VDMI has traditionally been attributed to physical constraints such as the enlarging uterus but this role may be overemphasized. The dip coincides with changes in reproductive status, fat mass and metabolic changes in support of lactation. A number of metabolic signals may have a role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines and neuropeptides such as neuropeptideY, galanin and corticotrophin-releasing factor. During late pregnancy and lactation, energy requirements increase considerably. Fetal energy requirements on day 250 of pregnancy have been calculated at 2.3 Mcal/d for Holstein cows. During lactation, energy requirement is increased to 26 Mcal net energy in cows producing 30 kg milk/day. Major changes in metabolism occur to cope with this increase in nutrient requirements. On a diet high in energy density, pregnant heifers will have a relatively high plasma concentration of glucose and a relatively low concentration of NEFA. Post partum, the concentration of NEFA is high while glucose is reduced. These changes reflect the large need for glucose and nutrients by the mammary gland and that dairy cows increase the use of lipid as a source of energy to support lactation. The NEFA begins to rise 2–4 weeks before calving and peaks at calving or during the first week of lactation. Glucose increases during the last week before calving and drops abruptly post partum to reach a minimum of 1–3 weeks into lactation. Post partum changes in the plasma concentration of BHBA are generally opposite those of glucose.

**Immunosuppression during the transition period**

In addition to the adaptations in classical metabolism which occurs during the transition period, cows during this period undergo a period of reduced immunological capacity during the periparturient period. The immune dysfunction is broad in scope, affects multiple functions of various cell types and lasts about 3 weeks prior to calving until about 3 weeks after calving. Cows during this period are more susceptible to mastitis. The etiology of periparturient immunosuppression is multifactorial and not well understood but seems to be related to physiologic changes associated with parturition and the initiation of lactation and to metabolic factors related to these events. Glucocorticoids are immunosuppressants, are elevated at parturition and have been postulated to have a role in periparturient immunosuppression.

The effects of parturition on cytoplasmic glucocorticoid expression (GR) in neutrophils and the correlation of the expression with serum cortisol concentration and total leukocyte count and neutrophil counts in periparturient cows has been examined. Neutrophils from periparturient cows had a 49% reduction in GR expression at calving, compared with GR expression 2–4 weeks before calving and 39% reduction, compared with neutrophils from cows in mid-pregnancy. The reduction in neutrophil GR expression is detectable 1 week before calving and most severe at calving and 24 h after calving. Multiparous cows have prolonged GR down-regulation of their neutrophils compared with primiparous cows which may be associated with a higher incidence of mastitis in older cows. Serum cortisol concentrations and total leukocyte and neutrophil counts were significantly increased at calving and returned to baseline value by 24 h after calving. Thus, a cortisol-induced neutrophil GR down-regulation and neutrophil migration dysfunctions occur in periparturient dairy cows. There is impaired expression of adhesion molecules and decreased migration capacity of blood neutrophils. Rapid recruitment of neutrophils into newly infected mammary tissue is the key immunologic defense against mastitis-causing pathogens in ruminants.

Experimentally, nonesterified fatty acids in vitro significantly reduces immunosuppressiveness of mononuclear cells of ewes which may be associated with the impairment of cell-mediated and humoral immunity in sheep and cattle with ketosis.

Because vitamin E is a fat-soluble membrane antioxidant which enhances the functional efficiency of neutrophils by...
protecting them from oxidative damage following intracellular killing of ingested bacteria, the parenteral administration of vitamin E has been explored for the prevention of peripartum diseases such as retained placenta, metritis, and clinical mastitis. Only cows with marginal vitamin E status (serum α-tocopherol <2.5 × 10⁻³ g/L) 1 week before calving will have a reduction in the risk of retained placenta following a subcutaneous injection of 3000 IU of vitamin E.22 In cows with an adequate level of serum vitamin E there was no reduction and primiparous animals were most likely to benefit from vitamin E 1 week before parturition. The associations between peripartum serum vitamin E, retinol and β-carotene in dairy cattle and disease risk indicated that an increase in α-tocopherol of 1 µg/mL in the last week prepartum reduced the risk of retained placenta by 20%, whereas serum NEFA concentrations ≥ 0.5 mEq/L tended to increase the risk of retained placenta by 80%. In the last week prepartum, a 100 ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early lactation clinical mastitis.

Diseases of lactation

In the next phase of the production cycle, parturition is followed by the sudden onset of a profuse lactation which, if the nutrient reserves have already been seriously depleted, may further reduce them to below critical levels and clinical metabolic disease then occurs. The essential metabolite which is reduced below the critical level determines the clinical syndrome which will occur. Most attention has been paid to variations in balances of calcium and inorganic phosphates relative to parturient paresis; magnesium relative to lactation tetany; blood glucose and ketones and hepatic glycogen relative to ketosis; and, potassium relative to hyperkalemia on cereal grazing, but it is probable that other imbalances are important in the production of as yet unidentified syndromes.

The vast majority of production diseases of dairy cows occur very early in lactation. At this time, the cow is producing milk at a rate which is substantially less than her maximum. In terms of rate, high and low milk yielding cows are producing rather similar amounts at this time. However, in terms of acceleration, the change in milk yield per day, it is highest immediately after calving.

During the succeeding period of lactation, particularly in cows on test schedules and under the strain of producing large quantities of milk, there is often a variable food intake, especially when pasture is the sole source of food and instability of the internal environment inevitably follows. The period of early lactation is an unstable one in all species. Hormonal stimulation at this stage is so strong that nutritional deficiency often does not limit milk production and a serious drain on reserves of metabolites may occur.

Recombinant bovine somatotrophin.

Recombinant bovine somatotrophin (rBST) is a synthetically derived hormone that may be identical to naturally occurring bovine growth hormone, or slightly modified by the addition of extra amino acids. The product was approved in the USA in 1993 and its use began commercially in 1994 in dairy herds to increase milk production.24 A meta-analysis of the effects of rBST on milk production, animal health, reproductive performance and culling has been done in Canada and the drug was not approved for use. Recombinant bovine somatotrophin was found to increase milk production by 11.3% in primiparous cows and 15.3% in multiparous cows; although there was considerable variation between studies. While some statistically significant effects on milk composition (percentage of butterfat, protein, and lactose) were found, they were all very small. Treatment increased dry matter intake by an average of 1.5 kg/d during the treatment period and dry matter intake remained elevated on into the first 60 days of the subsequent lactation. Despite the increase in dry matter intake, treated animals had lower body condition scores at the end of the treatment period and the reduced scores persisted through until the start of the subsequent lactation. Recombinant bovine somatotrophin increased the risk of clinical mastitis by approximately 25% during the treatment period but there was insufficient data to draw firm conclusions about the effects of the drug on the prevalence of subclinical intramammary infections. Use of rBST increased the risk of a cow failing to conceive by approximately 40%. For cows which did conceive, there was no effect on services per conception and only a small increase in average days open. Use of the drug had no effect on gestation length, but the information about a possible effect on twinning was equivocal. Cows treated with rBST had an estimated 55% increase in the risk of developing clinical signs of lameness. There appeared to be an increased risk of culling in multiparous cows. Use of the drug in one lactation period appeared to reduce the risk of metabolic diseases (particularly ketosis) in the early period of the subsequent lactation. The reproductive effects of the drug could be controlled by delaying its use until the cows were confirmed pregnant.

In 1998, an expert panel appointed by the Canadian Veterinary Medical Association at the request of Health Canada, found a number of legitimate animal welfare concerns associated with the use of rBST. In 1999, Health Canada announced that it would not approve the use of rBST for sale in Canada. The Royal College of Physicians and Surgeons of Canada Expert Panel on Human Safety of rBST found no biologically plausible reason for concern about human safety if rBST were to be approved for sale in Canada.

In 1999, a working group from within the Scientific Committee on Animal Health and Animal Welfare of the European Commission presented a more extensive report which summarized similar results and engaged substantive discussion of animal welfare from the points of view of physiologists and epidemiologists. It concluded that rBST should not be used in dairy cattle. In October 1999, the European Commission banned the use of and marketing of rBST in the European Union as of 1 January, 2000.25 The animal welfare aspects of the use of rBST and the laws and ethical issues, data analysis, epidemiologic evaluation, and public policies involved for the different reasons made in the USA, Canada, and Europe with regard to the use of rBST in dairy cattle have been reviewed and discussed elsewhere.25

A comprehensive econometric model was developed to evaluate the potential effects of rBST approval on the Japanese dairy industry.27 Simulation results indicate that rBST approval would accelerate structural change in Japan’s dairy industry toward fewer, larger farms. Negative effects of rBST on farm income are projected to be more severe for smaller farms, because of higher costs, lower profit-earning ability, lower milk yields, and lower adoption rates of rBST. Larger farms would benefit from rBST adoption if milk demand is maintained. However, if public health concerns about rBST induce significant milk demand decreases, even the largest farms’ income and cow numbers would decrease. Thus, Japan’s dairy industry could be caught in a double downward spiral of declining milk prices and production.

Breed susceptibility

The fact that some dams are affected much more by these variations than others is probably explainable on the basis of variations in internal metabolism and degree of milk production between species and between individuals. Between groups of cows, variations in susceptibility appear to depend on either genetic or management factors. Certainly, Jersey cows are more susceptible to parturient paresis than cows of other breeds and Guernseys seem to be more susceptible to
ketosis. Even within breeds, considerable variation is evident in susceptibility between families. Under these circumstances, it seems necessary to invoke genetic factors, at least as predisposing causes.

Management practices
The management practices of most importance are housing and nutrition. In those sections of North America where cattle are housed during the winter and in poor pasture areas, ketosis is prevalent. In the Channel Islands, local cattle are unaffected by lactation tetany, whereas the disease is prevalent in the UK. In New Zealand, metabolic diseases are complex and the incidence is high, both probably related to the practice of having the cows calve in late winter when feed is poor and to the practice of depending entirely on pasture for feed and to the high proportion of Jerseys in the cattle population.

A knowledge of these various factors is essential before any reasonable scheme of prevention can be undertaken. It should also indicate that although the more common disease entities are presented in this chapter, there is high probability that a disturbance of more than one of the metabolites mentioned may occur simultaneously in the one animal and give rise to complex syndromes which are not described here. The disease entities dealt with must be considered as arbitrary points in a long scale of metabolic disturbances.

Occurrence and incidence of metabolic diseases
A knowledge of the etiological and epidemiological factors involved will help in understanding the occurrence and incidence of the various metabolic diseases. Largely because of variations in climate, the occurrence of metabolic disease varies from season to season and from year to year. In the same manner, variations in the types of disease occur. For example, in some seasons, most cases of parturient paresis will be tetanic; in others, most cases of ketosis will be complicated by hypocalcemia. Further, the incidence of metabolic disease and the incidence of the different syndromes will vary from region to region. Ketosis may be common in areas of low rainfall and on poor pasture. Lactation tetany may be common in colder areas and where natural shelter is poor. Recognition of these factors can make it possible to devise a means whereby the incidence of the diseases can be reduced.

The metabolic diseases, because of high prevalence and high mortality rate, are of major importance in some countries, so much so that predictive systems are being set up. Rapid analysis of stored feed samples, pasture and soil is commonly used in Europe and North America but the interesting development has been the recognition of ‘production diseases’ and the consequent development of metabolic profile tests, particularly in the UK and in Europe.

Production diseases
The term ‘production disease’ includes those diseases previously known as ‘metabolic diseases’, such as parturient paresis (milk fever), hypomagnesemia, acetonemia, and perhaps some other conditions, all of which are attributable to an imbalance between the rates of input of dietary nutrients and the output of production. When the imbalance is maintained, it may lead to a change in the amount of the body’s reserves of certain metabolites, or their ‘throughput’ and sufficiently large changes in throughput. The generalization applies principally to the hypoglycemics (ketosis) and hypomagnesemias and partly to the hypocalcemics. In these diseases, output is greater than input either because of the selection of cattle which produce so heavily that no naturally occurring diet can maintain the cow in nutritional balance, or because the diet is insufficient in nutrient density or unevenly balanced. For example, a ration may contain sufficient protein for milk production but contains insufficient precursors of glucose to replace the energy excreted in the milk. While agreeing with the generalization on which the term ‘production disease’ is based, we propose to continue to use the expression ‘metabolic disease’ because of common usage.

Relationship between lactational performance and health of dairy cattle
The literature on the relationship between lactational performance and health in dairy cattle has been reviewed. Based on a review of 11 epidemiological and 14 genetic studies there was little evidence that high yielding cows have increased risk of dystocia, retained placenta, metritis, and left-side displacement of the abomasum. The results for parturient diseases were inconsistent. While no phenotypical relationship between milk yield and the risk of ketosis and lameness was found, selection for higher milk yield will probably increase the lactational incidence risk for these diseases. Mastitis was the only disease where there was a clear relationship between milk yield and risk of infection. Continued selection for high milk yield will worsen this situation.

However, some authors claim that reviewing existing literature, even with structured literature selection, is inadequate to the task of elucidating the relationship between the lactational performance and risk of production diseases. The most notable feature of the literature evaluation is the large variability that exists between studies. This strongly suggests that there are important factors that need to be considered before meaningful conclusions concerning the relationship between lactational performance and risk of disease can be drawn.

COMPTON METABOLIC PROFILE TEST
Because of the emphasis on health management beginning in the 1970s, it became popular to explore methods of predicting the occurrence of metabolic disease in advance, so that control strategies could be considered and put into place. It was thought possible to predict the occurrence of production disease in a dairy herd by monitoring certain components of the blood on a regular basis. If the blood level fell below ‘normal’, it was assumed that intake needed to be increased to compensate for the negative balance created by excessive output.

The Compton metabolic profile is based on the concept that the laboratory measurement of certain components of the blood will reflect the nutritional status of the animal, with or without the presence of clinical abnormalities. For example, a lower than normal mean blood glucose in a group of dairy cows in early lactation may indicate an insufficient intake of energy which may or may not be detectable clinically. On a theoretical basis, the ability of the laboratory to make an objective assessment of the input–output (nutrient–productivity) relationships is an attractive tool for the veterinarian engaged in providing a complete health management service to a herd. The test would theoretically be able to detect the qualitative and quantitative adequacy of the diet of cows expected to produce a certain quantity of milk or return to estrus within a desirable length of time following parturition. A reliable test for the early diagnosis of nutritional deficiency or metabolic disease would be a major step forward in attempting to optimize livestock production and obtain maximum yields at minimum costs.

Some of the literature on metabolic profile testing in dairy cows has been reviewed. The use and interpretation of metabolic profiles in dairy herds in the Dairy Herd Health and Productivity Service (DHHPS) have been reviewed.
herds. The most valuable methods will be those which are sensitive enough to detect change before clinical or economic consequences are manifested. A major challenge in the application of metabolic profile testing is dealing with extraneous sources of variation. Successful management of extraneous variation requires sampling strategies based on animal grouping and testing of multiple animals. Larger herds may be more suitable because they are able to better design sampling strategies and to spread the costs of testing across more animals. In addition, the cost–benefit may be greater in larger herds because of the high cost of inadequate feeds and feeding programs. Statistical Process Control methods offer a unique approach to interpretation which may increase the usefulness of metabolic profiles.

There was considerable interest in the test following its earlier descriptions which simulated considerable field research. The results of the research have thus far indicated that the test may be useful only as an aid in the diagnosis of nutritional imbalance and production diseases. The results of the test are usually difficult to interpret without a careful conventional assessment of the nutritional status and reproductive performance of the herd and it appears doubtful that the test would reveal significant abnormalities which could not be detected using conventional clinical methods. There was considerable controversy about the practicality of the test. Because of costs of the test, the profile testing must be carefully planned with specific objectives. A regional diagnostic laboratory with automated analytical equipment should be available and this is often a major limiting factor. The test should not be undertaken unless normal values for each laboratory measurement are available from the population within the area. The results from the groups within the herd are compared with local population means. Metabolic profiles have also been suggested as an aid in the selection of superior individuals.

**METABOLIC PROFILES FOR INDIVIDUAL COWS**

The prediction of whether an individual cow is metabolically within normal range to undergo a stressful lactation at a high level of production would seem to be a useful undertaking. This could be particularly important under management conditions of heavy concentrate feeding, lead feeding, or zero grazing or even indoor housing. There are no well-established protocols for conducting such profile tests. The ‘parturition syndrome’, dealt with later under the ‘fat cow syndrome’ is considered to be predictable by the estimation of blood levels of total cholesterol and glutamic oxalate transaminase. In pastured cattle in New Zealand, the test has been found to be ineffective. Similar tests conducted on individual cows using many serum enzymes and electrolytes as indicators have not proved to be useful if used on only one occasion.

**Usefulness of metabolic profile testing**

Metabolic profiles in dairy cows were used initially in Britain in the 1960s. Success was limited primarily by the unjustified expectation that all biochemical concentrations in the blood of cows would reflect nutritional intake and status at all times. However, the practical value was found in the approach as an aid to nutritional management. Later, in the 1970s the approach was reassessed and reinstituted, culminating in a program for farmers evaluating health and productivity using metabolic profile testing as an integral part of a health management program involving a multidisciplinary approach. The system now depends on a team approach involving farmer, veterinarian, and agricultural adviser. The blood testing part, if useful information is to be obtained, depends critically on following a set of firm criteria for selection of small groups of typical cows within each herd, the timing of testing in relation to concentrate feeds, feed changes, and stage of lactation and the collection of other data about the cows such as body weight and condition, productivity and feeding. The successful approach has been to look, following specific times of nutritional change, at metabolite levels in strictly defined small representative groups of cows within each herd in conjunction with information on body condition and weight, milk performance, and feeding. Comparison with optimum values, the degree of variation from them and comparisons between groups within herds have allowed information about nutritional constraints on productivity to be made available to farmers more quickly and more specifically than by other means.

Most metabolic profile testing has been used in temperate climates. The effectiveness of the technique for identifying constraints on productivity in small herds in tropical and sub-tropical countries has been examined. The study involved 13 projects with 80 cows in each, done in six Latin American, six Asian, and one southern European countries. Data were also collected on feeding, body condition score and weight change, parasitism, and reproduction. In Chile, Mexico, Paraguay, Philippines, Uruguay, and Venezuela, globulin levels were high in >17% of cows samples on each occasion. In Paraguay, 49% of cows had high globulin levels at 2–3 months after calving. This suggests that inflammatory disease was present although this was not always investigated. In all countries except Mexico and Venezuela, high β-hydroxybutyrate levels before calving in many cows highlighted the presence of body condition loss in late pregnancy, an important potential constraint on productivity and fertility. Fewer cows had high BHβ levels in lactation, whereas change in BCS and weight was more sensitive for measuring negative energy balance. Urea concentrations were low in only small numbers of cows suggesting that dietary protein shortages were not common. Albumin levels were low mainly in cows where globulin values were high and therefore did not provide additional information. In China, pregnant yaks over winter had high BHβ and low albumin values, suggesting that they were seriously underfed. This resulted in a successful nutritional intervention in the following winter. Inorganic phosphorus values were within the reference range in most countries most of the time, suggesting, contrary to expectation, that this mineral was not commonly a constraint. In summary, the use of metabolic profile testing proved valuable in drawing attention to important potential constraints on productivity in dairy cows in tropical and subtropical environments and in confirming those which were not.

Metabolic profile testing has been used for the prevention of periparturient diseases in dairy cows in Japan. In herds with a high incidence of periparturient disease, low blood values of hematocrit, albumin, glucose, cholesterol, calcium, and magnesium were observed in the dry period. The values correctly diagnose malnutrition as the cause of the periparturient diseases. Following feeding management changes, there was a low incidence of these diseases and the metabolic profiles were normal indicating that feeding management had improved. Because the traditional metabolic profile test is difficult to apply to peripartum cows because they are in state of physiological abnormality and the results are difficult to interpret, doing a test every 10 days during the dry and lactation periods has been evaluated. The criteria were interpreted by the deviations from the reference mean values of metabolites rather than the actual values. The body condition score, albumin, blood urea nitrogen, glucose, total cholesterol, non-esterified fatty acids, y-glutamyl transpeptidase, and aspartate aminotransferase, fluctuated during the dry and early lactation periods and there were large changes in the hematocrit, blood urea nitrogen, total cholesterol, and
magnesium and high nonesterified fatty acids in herds with a high incidence of peripartum diseases.

The values of the variables which deviated from the reference values for the metabolic profile components were able to assess milk production and feeding which is a practical tool for auxiliary feeding evaluation.39

The Dairy Herd Health and Productivity Service (DHPPS) in the UK offers the opportunity for veterinarians to lead a multidisciplinary team which can monitor health, fertility, and production and can plan, when necessary, corrective action.38

Metabolic profiling and body condition scoring found that at least a third of the cows sampled were mobilizing excess fat during the transition from the dry period to early lactation. Improving both health and nutrition, before and after calving, would improve reproductive performance in many herds. A team approach, with farmers, veterinarians, nutritionists, and other advisors working together with well-defined goals and objectives, is necessary if progress is to be made in improving reproductive performance. High milk yields cannot always be the excuse for suboptimal fertility.38

**Biological and statistical basis for herd testing**

The interpretation of herd-based tests for metabolic diseases is different from interpreting laboratory tests for metabolites from individual cows.39 Test results from individual cows are interpreted by comparing the value to a normal reference range established by the laboratory that did the testing. Normal ranges are often derived by calculating a 95% confidence interval (or a similar statistic) of test results from 100 or more clinically normal animals.

Herd test results for metabolic diseases can be interpreted as either the mean test result of the subgroup sampled or as the proportion of animals above or below a certain cut point within the subsample. If a metabolite is associated with disease when it is above or below a biologic threshold (cut point) then it should be evaluated as a proportional outcome. For example, subclinical ketosis in dairy herds can be monitored by testing for β-hydroxybutyrate (BHBA) or other ketone bodies in blood or milk. Subclinical ketosis is a threshold disease and cows are affected only when ketone concentrations are elevated. Blood BHBA concentrations above 1400 μmol/L is the most commonly used cut point for subclinical ketosis. Early lactation cows with BHBA concentrations above this cut point are a threefold greater risk to develop either clinical ketosis or displaced abomasum. Non-esterified fatty acids (NEFA) concentrations in blood are an indicator of negative energy balance in prepartum cows. Elevated NEFAs before calving are associated with increased risk for displaced abomasum after calving. A threshold above 0.400 mEq/L for cows between 2 and 14 days of calving is suggested as an appropriate cut point.

It is also necessary to determine the alarm level for the proportion of animals above or below the described cut point. The alarm level is determined from research results or clinical experience. The suggested alarm level proportions for BHBA with a cut point of =1400 μmol/L is >10% and for NEFAs with a cut point of =0.400 mEq/L is >10%.

Herd-based testing is useful only when a sufficient number of cows within the herd are tested, which gives reasonable confidence that the results truly represent the entire population of eligible cows in the herd. The minimum sample size for herd-based tests with proportional outcomes is 12 cows. Cows to be sampled need to be selected from the appropriate eligible or at risk group.

The ‘proper’ use of metabolic profiles depends on care with the timing of blood tests, the selection of cows to be included and the collection and use of background information about the farm, feeding, and feeding system and physical state and performance of the cows.40

As of 2005, for 5 years the Dairy Herd Health and Productivity Service (DHPPS) in the UK have been using the metabolic profile approach as an aid to the management of dairy cow nutrition. Effectively the approach has been to ‘ask the cows’ what they think of their nutrition – by following a set of ‘rules’ on timing, cow selection and the use of background information.39 The involvement of a team approach at the farm, including private veterinarian and nutritional adviser, to put the findings in the correct context and to identify the appropriate responses has been vital. Data on health and fertility from many of these farms has also been collected.

**Variables in dairy-herd metabolic profile testing**

**Energy balance**

Non-esterified fatty acids (NEFAs)

Non-esterified fatty acids are a sensitive indicator of energy balance. They are useful for monitoring energy status of dry cows in the last month of gestation, when rapid changes in energy balance status may not be detectable from changes in body condition score.31 High values of NEFAs indicate negative energy balance which occurs in animals which are inappetant for any illness.

The serum levels of NEFAs have been monitored in dairy cows as predictors of displaced abomasum.41 In cows with LDA, mean NEFA concentration began to diverge from the mean in cows without LDA 14 d before calving, whereas mean serum β-hydroxybutyrate (BHBA) concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with risk of LDA. Between Day 0 and 6 days after calving, cows with NEFA concentration of ≥0.3 mEq/L were 3.6 times more likely to develop LDA after calving. Strategic use of metabolic tests to monitor transition dairy cows should center on NEFA. In the last week prepartum and BHBA in the first week post partum.41 In another study, cows with plasma NEFA >3.0 mEq/L between 3 and 35 days before calving were twice as likely to subsequently have an LDA.42 In cows with serum BHBA ≥1200 or 1400 μmol/L in the first week post partum the odds of LDA were three and four times greater, respectively, than in cows with BHBA below the cut points.43

**Serum β-hydroxybutyric acid (BHBA)**

Serum BHBA concentrations are affected by energy and glucose balance and are a less specific indicator of energy balance than plasma NEFA. High values are associated with reduced milk production, increased clinical ketosis and LDA and reduced fertility.30 The gold standard test for subclinical ketosis is blood BHBA which is more stable ketone body than acetone or acetoacetate. Subclinical ketosis may start at serum concentrations above 1000 μmol/L. The alarm level for the proportion of cows above the cut-point of 1400 μmol/L has not been determined but it is suggested that no more than 10% subclinical ketosis should be tolerated in early lactation cows.35 Serum concentrations of 1400 μmol/L or greater in the first 2 weeks post-calving was found to cause a three-fold greater risk for cows to subsequently develop either clinical ketosis or LDA.44

Between 1 and 7 days post partum, retained placenta, metritis and increasing serum concentrations of BHBA and NEFA were associated with increased risk of subsequent LDA. The odds of LDA were eight times greater in cows with serum BHBA = 1200 μmol/L were 3.4 times more likely to develop LDA.45

**Blood glucose**

Blood glucose concentrations are usually lower in early lactation and during the winter months; in early lactation, there is a heavy demand for glucose and during the winter the energy intake is likely to be lower than necessary to meet requirements. One major cause of variation in blood glucose may be the major fluctuations in daily feed intake. Investigations of feed intake of dairy cows on commercial farms
have shown that concentrate dispensers are commonly incorrectly adjusted and errors of more than 50% in feed intake are sometimes found. In situations of marginal energy imbalance, blood glucose concentration levels may be unreliable as an index of the adequacy of energy intake. Several factors may cause short-term changes in blood glucose. Blood glucose decreases at the time of milk secretion, which makes sampling time critical. Blood glucose may also be influenced by the chemical nature of the carbohydrate and physical form of the feed and the roughage content of the feed. In addition, elevation of blood glucose has been associated with excitement and low environmental temperature.

There is some conflicting evidence about the relationship between mean values of blood glucose of a lactational group and insufficient energy intake and reproductive inefficiency. In some work, there is an expected relationship between low blood glucose and an increased incidence of ketosis. In others, the relationship is not clear, however there was a more consistent relationship between the actual energy intake as a percentage of requirement and the plasma non-esterified fatty acids, but this finding was not sufficiently reliable to be useful. The mean plasma glucose concentrations within 3 days before or after first service of cows which conceived on first service was higher than that of cows which returned, but the difference was only approaching significance at the 5% level and it is doubtful whether this could be of practical value. Although free fatty acids are more sensitive than blood glucose as an indicator of energy status of the lactating cow, the excessive variability of this relationship during early lactation limits its usefulness. Free fatty acids begin to increase several weeks prepartum, peak at parturition and decrease gradually to normal levels after several weeks of lactation. Blood glucose levels follow a similar pattern; however, there may be a period in early lactation when blood metabolite levels and particularly free fatty acids, are not entirely responsive to energy intake, but are perhaps under additional hormonal regulation.

Protein nutrition and metabolism

Urea nitrogen testing to evaluate protein

Milk urea N (MUN) can be used as a management aid to improve dairy herd nutrition and monitor the nutritional status of lactating dairy cows. Urinary N (UN) excretion has been shown to have a positive linear relationship with MUN. Elevated MUN indicates excess protein has been fed to the dairy cow for her given level of production. When adequate energy is in the diet of ruminants, both blood urea nitrogen and milk urea nitrogen have long been known to be indicators of their protein status. Increases in plasma urea concentration and ammonia occur primarily as a result of inefficient nitrogen utilization. An excess of rumen degradable protein results in an increase in the concentration of rumen ammonia, which is absorbed through the rumen wall and transported to the liver, where it is converted to urea. The catabolism of body protein for gluconeogenesis can also result in the production of ammonia, which is also converted to urea in the liver. Plasma urea has been the most commonly used blood constituent for monitoring protein status and intake. Urea moves passively from the blood into the milk and there is a close relationship between its concentrations in the two fluids. Thus, milk urea has been used as a non-invasive substitute for the measurement of the protein status and protein intake of ruminants. There is also a relationship between urinary nitrogen excretion (UN) and milk nitrogen (MUN).

It has been estimated that when dietary energy remained unchanged, milk urea concentration increased by 12–18 mg/L for each additional 60 g of digestible crude protein fed to cows already receiving adequate protein.5 Milk samples should be submitted to an accredited diagnostic laboratory for MUN analysis. The Azotest Strip, an on-farm dipstick test, lacks accuracy and is not recommended.46

The milk urea nitrogen target concentrations for lactating dairy cows fed according to National Research Council Recommendations have been evaluated.47 Target N ranges from approximately 150 to 200 g/d. The target MUN concentrations are now 8.5–11.5 mg/dL for most dairy herds compared with the previous target concentrations of 12–16 mg/dL.48,49 Milk urea, together with percentage milk protein is being used increasingly as an indicator of the dietary protein-energy balance. In many European countries and North American states and provinces, UREA analyses are available in Dairy Herd Improvement (DHI) programs. The somatic cell count did not lower UREA concentrations in quarters with elevated SCC.49 The time of sampling can have a significant effect on UREA concentrations; the highest in the morning and the diurnal pattern was not influenced by intrinsic factors like parity, days post partum or daily milk yield.49 The levels were significantly increased after refrigeration for 1 week.

Providing dairy farmers with information regarding their herd's MUN should result in more accurate feed management and change toward target values. A survey of dairy farmers in a region in Virginia and Maryland indicated that 89.5% did not routinely use MUN prior to participating in the project, but most (88%) extension agents and nutritionists in the region recommended it. Providing MUN results and interpretive information to farmers changed feeding practices and subsequent MUN results.50

High milk yield in dairy cows is dependent on high intakes of dietary protein (17–19% crude protein) and energy. However, in the ruminant, high protein diets may be associated with reduced reproductive performance. In the UK, dairy cattle are housed over the winter months and turned out to graze in the spring. Spring turnout coincides with the first flush of new pasture growth which can contain very high levels of rapidly degradable protein. Many dairy herds in the UK experience a short-term fall in pregnancy rates at spring turnout. It has been suggested that the problem at turnout is worst on pastures heavily fertilized with nitrogenous fertilizers.

Several reviews of the literature have examined the effect of protein nutrition on reproduction in dairy cows. The reported effect of high nitrogen intake on fertility is inconsistent. Experimentally, the ingestion of a high level of degradable protein commencing 10 days before insemination in lactating dairy cows had no effect on reproductive performance of the lactating high yielding dairy cow.51 The relationship between milk urea concentration and the fertility of dairy cows from 250 herds in the UK found no relationship between bulk milk urea concentration and fertility, or between changes in bulk milk urea concentrations and fertility.45 Also, the relationship between the milk urea concentration 5 days after service and the fertility of individual cows was examined. There was no significant difference between the milk urea concentration of the cows which became pregnant and those that did not.

A meta-analysis of the literature evaluated the associations between dietary requirements for protein for dairy cattle, the metabolism of protein in cattle, factors influencing the degradability of protein in ruminant feeds, and factors influencing milk urea concentrations.52 There are good correlations between dietary protein intake and rumen ammonia, blood urea, and milk urea concentrations. The effect of increasing dietary protein on milk production has been defined through feeding trials and modeling methods used to provide feeding standards. Ryegrass clover pastures provide feed in many of the temperate dairy regions of the world and for much of the year pasture crude protein may exceed 30%, of which a high proportion is rapidly degradable. High dietary protein intakes may have a negative effect on reproductive efficiency.

Elevated MUN indicates excess protein is being absorbed through the rumen wall and transported to the liver, where it is converted to urea. The catabolism of body protein for gluconeogenesis can also result in the production of ammonia, which is also converted to urea in the liver. Plasma urea has been the most commonly used blood constituent for monitoring protein status and intake. Urea moves passively from the blood into the milk and there is a close relationship between its concentrations in the two fluids. Thus, milk urea has been used as a non-invasive substitute for the measurement of the protein status and protein intake of ruminants. There is also a relationship between urinary nitrogen excretion (UN) and milk nitrogen (MUN). It has been estimated that when dietary energy remained unchanged, milk urea concentration increased by 12–18 mg/L for each additional 60 g of digestible crude protein fed to cows already receiving adequate protein.5 Milk samples should be submitted to an accredited diagnostic laboratory for MUN analysis. A meta-analysis of the literature evaluated the associations between dietary requirements for protein for dairy cattle, the metabolism of protein in cattle, factors influencing the degradability of protein in ruminant feeds, and factors influencing milk urea concentrations.52 There are good correlations between dietary protein intake and rumen ammonia, blood urea, and milk urea concentrations. The effect of increasing dietary protein on milk production has been defined through feeding trials and modeling methods used to provide feeding standards. Ryegrass clover pastures provide feed in many of the temperate dairy regions of the world and for much of the year pasture crude protein may exceed 30%, of which a high proportion is rapidly degradable. High dietary protein intakes may have a negative effect on reproductive efficiency.
performance in lactating dairy cows, but the role of milk urea as a predictor of fertility needs further definition given the high conception rates in many Australasian dairy herds.52 High intakes of dietary protein may induce adaptations in urea metabolism and the negative relationship identified between high intakes of dietary protein and fertility for Northern Hemisphere dairy herds may not necessarily apply in Australasian dairy herds. Because of the potential for cows to adapt to high protein diets, the use of single milk urea determination on a herd will have limited value as an indicator of nutritional status and little value as a predictor of fertility.53 The differing observations among various production systems indicate the need for careful consideration in applying recommendations for diet protein management based on milk urea concentrations. Milk urea determinations may, however, have value, particularly when used in conjunction with other herd and nutritional data to assess the protein nutrition of dairy herds. It is highly unlikely that single or even serial determinations of milk urea in single cows or bulk tank milk will have a high predictive value for determining the risk of conception in the cow or herd.54

**Serum albumin**

Serum albumin is related to protein status of the animal. Lactation stage has a substantial effect on serum albumin. Animals should be grouped into dry cows, early lactation (1–10 weeks) and later lactation. Minimal values for dry cow means are from 2.9 to 3.1 g/dL, for recently calved cows from 2.7 to 2.9 g/dL, and 3.0 to 3.2 g/dL for cows in later lactation.

**Hematocrit**

The hematocrit can be used as a general reflection of health. In most dairy herds, a low hematocrit may be a reflection of suboptimal energy and protein nutrition. Mean values of packed cell volume (PCV), hemoglobin and serum iron are consistently higher in non-lactating cows than in lactating cows. Parasitism causing blood loss will result in a low hematocrit. The hematocrit varies with lactation stage, being highest in dry cows and lowest in early lactation. Cows should be grouped by lactation stage.

**Mineral nutrition**

**Serum inorganic phosphorus**

Serum inorganic phosphate levels tend to fall following long-term insufficient dietary intake and hyperphosphatemia may occur in cattle grazing on highly fertilized pasture.

**Serum calcium**

Serum calcium levels vary only within narrow limits and are not sensitive indicators of input–output balance. However, abnormally low levels in late pregnancy indicate a dangerous situation.

**Serum magnesium**

Serum magnesium levels are usually low during the winter months and subclinical hypomagnesemia exists in many herds, especially pregnant beef cattle. This can be converted into clinical hypomagnesemia with a sudden deprivation of feed or a sudden fall in environmental temperature. Supplementation of the diet with magnesium salts is protective.

**Serum sodium**

Low levels of serum sodium occur in early lactation in cows grazing on summer pastures without supplementation with salt. Levels down to 135 mmol/L may be associated with dehydrated appetite and polydipsia and polyuria.

**Serum potassium**

Serum potassium levels have been difficult to interpret because the levels of the electrolyte in serum are not necessarily indicative of potassium deficiency. Its normal serum concentration is much more variable than sodium and its average concentration in roughages of all kinds is nearly always in excess of requirements; any abnormalities are usually in the direction of excess.

**Timing of blood tests**

**In relation to feed changes**

As changes in the diet of ruminants require changes in the character of rumen activity, blood samples for metabolic profiles should not be done until 2 weeks after a major change and activity has had time to adapt. Minor changes such as an increase in the quantity of an existing component or in access to the same ration do not require a wait of more than 7–10 days. Changes in forage type, such as turnout to pasture, housing, or the introduction of silage require the full 2 weeks. The same applies for introduction of concentrates or of a new type of concentrate.

**In relation to feeding**

There can be changes in biochemical values in blood associated with feeding. These are most marked in cows receiving all their concentrate ration at milking time. In such cases, 2 h should be allowed to elapse after milking before blood sampling. In circumstances where the major part of the concentrate input is mixed with the forages and is available for most of each 24 h, the timing of tests in relation to feeding is less critical. If lower yielding mid lactation cows are included (see later), their results can be used as a check to see if there is an effect of feeding on the biochemical values in the blood samples.

Cows should not be separated at milking time and confined for hours without access to food waiting for blood sampling as this can also affect the results.

**In relation to calving pattern and seasonal feeding changes**

The cow in early lactation is the most important because what happens to her in the first few weeks after calving has the major influence on her subsequent productivity, including her future fertility efficiency. Therefore, blood sampling for metabolic profiles should be carried out at the beginning of each new calving season, with the first cows checked so that the majority can benefit from the information derived.

Of equal importance is the need to test as soon as possible after the introduction of a new ration, so that evaluation of the cows' biochemistry can be made available as quickly as possible, i.e. what the cows, the end users, think of the ration.

Therefore planning of metabolic profile tests needs to be done in advance and should take in to account both expected calving pattern and feed changes. Without planning along these lines, time may be lost and productivity with it.

**Selection of cows**

Picking appropriate cows for blood sampling is very important. This is because some of the metabolites looked at, particularly those relating to energy balance, can quickly return to the optimum range as cows adapt themselves, including their productivity, to a nutritional constraint. It is possible for cows to experience a significant energy deficit in the first 2–3 weeks of lactation because of intake problems, lose excessive body condition, perhaps modify their milk yield, and have their subsequent fertility efficiency suppressed but yet still arrive at 4 weeks calved with all biochemical measurements within the optimum range. This is because the common appetite constraint of the new calved has worked its way out and there is plenty of food available for lower performance than anticipated. If blood is sampled at 4 weeks calved or longer, a farmer could see thin, under-producing cows with poor fertility but with nothing abnormal about their biochemistry. Thus, the farmer would be entitled to feel the metabolic profile test was of no value. However, if those cows had been blood sampled at 14 days calved instead of 27, the blood results would have been quite different and would have identified the nutritional constraint on productivity.55

The 'Rules' for metabolic profiling of dairy cattle recommend sampling from the following groups:

- Performance in lactating dairy cows, but the role of milk urea as a predictor of fertility needs further definition given the high conception rates in many Australasian dairy herds.52 High intakes of dietary protein may induce adaptations in urea metabolism and the negative relationship identified between high intakes of dietary protein and fertility for Northern Hemisphere dairy herds may not necessarily apply in Australasian dairy herds. Because of the potential for cows to adapt to high protein diets, the use of single milk urea determination on a herd will have limited value as an indicator of nutritional status and little value as a predictor of fertility.53 The differing observations among various production systems indicate the need for careful consideration in applying recommendations for dietary protein management based on milk urea concentrations. Milk urea determinations may, however, have value, particularly when used in conjunction with other herd and nutritional data to assess the protein nutrition of dairy herds. It is highly unlikely that single or even serial determinations of milk urea in single cows or bulk tank milk will have a high predictive value for determining the risk of conception in the cow or herd.54
Early lactation (EL): between 10 and 20 days of lactation  
Mid lactation (ML): between 50 and 120 days of lactation  
Dry period (D): between 7 and 10 days of calving.

Individual variations in biochemical values are such that single cows should not be tested. **Groups of no less than five should be sampled.** They should not be picked at random but rather should be typical, average cows of their stage of lactation. Cows with extremes of performance – either very high or very low – should not be selected. Cows with problems should also not be included because the type of analysis carried out is not designed to clarify individual problems. It is important to make all this clear to farmers in advance because they cannot be expected to appreciate the limitations of the analyses made. Experience in the Dairy Herd Health and Productivity Service in the UK suggests that selecting cows for metabolic profiles may be best done by the veterinarian in advance of the test after looking at the calving and production records. If there is a specific concern such as a poor conception rate, farmers may expect only cows which have failed to conceive to be sampled. This hardly ever delivers helpful information as any nutritional constraints have by then been compensated for and blood biochemical values are usually within optimum ranges. The best approach may be to include such cows as the mid-lactation group.

**Early lactation group (EL)**

The definition used for this group is most critical for the reasons given in the previous paragraph. Since the original Compton metabolic profile where high yielding cow was used as the definition, the importance of this group has become increasingly apparent. The definition also has had to be changed to take into account changes in farm practice. The way cows are fed now – total mixed rations, increased out of-parlor concentrate feeding – has reduced the time after calving by when they can adapt themselves to an unsatisfactory diet. **To be sure of detecting the presence of an energy constraint in particular, blood sampling should be carried out between 10 and 20 days calved** – less than 10 days and the yield is still too far below peak for the test to be a realistic one for early lactation performance; more than 20 days and some cows will be thin, unproductive and subfertile but have compensated for their nutrition and they may have normal blood metabolite values.

**Mid-lactation group (ML)**

Some cows which are passed the period of peak yield and so passed the greatest period of potential nutritional stress should always be included. **They should be between 50 and 120 days calved** so that they are still relatively high yielding. This group provides a within-herd comparison with the early lactation cows. Without this it is very difficult to distinguish between problems caused by constraints on intake of food or protein and energy content; to identify changes in biochemical values caused by mistiming of tests in relation to feeding or by oddities in the diet such as silage with a high butyric acid content; and to make judgments on concentrate forage usage within the herd.

**Dry cow group (D)**

As the dry period is so important to the success of the following lactation, blood sampling to make sure nutrition is adequate is essential. However, the nature of the measurements which can be made means that primarily cows in the last 7–10 days of pregnancy should be sampled. Cows tested with longer to go than that tend to have normal measurements of energy balance even though they can still get in to difficulty. This is because the period of greatest risk is when the volume of the pregnant uterus increases to the point that it can seriously inhibit food intake. It follows that, in a seasonal calving herd, the first dry cows which come in to these last 7–10 days ought to be blood sampled, so that the information can be used for the benefit of the others still to come in to the maximum risk period.

Blood sampling a group of dry cows with 1 month or longer to go to calving at the same time can sometimes provide a useful within herd comparison with respect to energy balance. It may also identify the presence of dietary protein inadequacy – specifically rumen degradable – in the early part of the dry period.

In the DHHPS program, a majority of farms do metabolic profiles 3–4 times a year at critical times as a check ‘ask-the-cows-what-they-think’ exercise. Thus metabolic profiles as part of a pro-active preventive health and productivity programme. Some of the larger farms may do more than 10 tests a year to cover feed changes and to check on the success of any corrective action.

In the DHHPS program, a standard DHHPS metabolic profile includes analysis on blood plasma for β-hydroxybutyrate (BHB), glucose, non-esterified fatty acid (NEFA), urea-nitrogen (urea N), albumin, globulin, magnesium, and inorganic phosphate. Analyses for copper and glutathione peroxidase (GSHPx) are done on approximately one-third of samples received and thyroxine T4 on even fewer. Biochemical analysis is performed using two Bayer Opera auto-analysers, with standard internal controls. It also employs an independent, external quality control system. Derivation of optimum metabolite values are summarized in Table 29.2. They are BHB <1.0 mmol/L in cows in milk, <0.6 mmol/L in dry cows; glucose >3.0 mmol/L; NEFA <0.7 mmol/L in cows in milk and <0.5 mmol/L in dry cows; ureaN >1.7 mmol/L; albumin >30 g/L; globulin <50 g/L; magnesium >0.7 mmol/L; inorganic phosphate >1.3 mmol/L; copper >9.2 μmol/L; glutathione peroxidase (GSHPx) >50 U/g HB; thyroxine T4 >20 mmol/L.

**Energy.** The data in Table 29.3 uses only the cows fitting precisely the definitions of EL, ML, and D. It shows that, overall, an average of 30% EL cows had metabolite results reflecting satisfactory energy status as did 61% of ML and 43% of D. In both EL and ML groups, glucose is the metabolite most commonly outside its optimum range, followed by BHB and NEFA. The percentage of NEFA values above optimum is low in ML cows. The most common finding is high BHB and low glucose in the same cow. In tests showing most cows in an EL group with results like that, there is usually one or two with high NEFAs as well. Some EL cows show low ureaN only or high NEFA. Where low glucose only predominates in EL cows, ML cows often show the same picture.

**Protein.** UreaN results in Table 29.3 show that the EL stage is more vulnerable to low values than later in lactation, even though the cows would have been on the same diets in virtually every case. In fact an even greater average percentage in 1361 cows blood sampled between 0 and 9 days after calving over the 5 years showed low ureaN.

The proportion of low ureaN results in D cows is high (Table 29.3). In addition to the category shown of 10 days or less before calving, 4335 cows were sampled at more than 10 days prepartum over the 5 years and 22% of them had low ureaN values too.

Results outside the optimum ranges for albumin (0.6%), magnesium (2.5%), inorganic phosphate (10%), copper (10%), GSHPx (3%) are relatively uncommon. Thyroxine T4 analysis was carried out in 836 samples on specific request and only 3% were below optimum.

Background information
So that full value can be obtained by the farmer from the metabolic profile approach, information about the cows and the farm should accompany the blood samples to the laboratory. This should include cow identification; last calving date for milkers/mergers; herd milk solids percentages. It is useful to have information on herd size, breed, feeding systems, and health and fertility. A note of what concerns the farmer has, if any, should also be made.

Interpretation of results at the farm
Circumstances where the diagnosis of a nutritional constraint from blood samples is clearly correct, but the cause(s) are unclear from a distance and could be many, are common. Therefore it is very important that a final interpretation of what is not working and what are the best and most economic solutions ought to be made at the farm with the information from the laboratory to hand. Farm advisory visits should be made as soon as the results are available and discussions made, including farm staff and any other advisers involved. Experience in the DHHPS suggests that such a team approach produces a more balanced strategy and is more beneficial than each party working in isolation.

Written advice
Any advice given should be recorded concisely in writing and copies given to all participants on the farm. This ensures that the agreed path is followed, keeps a record, and ensures that the fee is for something tangible.

Body condition score (BCS)
